- The model does not represent the appropriate interconnection of all potential surface water features with the aquifer. The areas in which there is probably significant interconnection of surface and ground water that is not treated by the model include:
    1. the Snake River from Shelley to the At Blackfoot gage, and
    2. Camas and Beaver creeks in the vicinity of Mud Lake.
- The model boundary does not conform to the boundary of the aquifer in all areas. Figure 11 shows the SRPAM1.1 model grid and the conformance to the RASA-defined boundary of the aquifer. The USGS Snake River Plain (Garabedian, 1992) followed the RASA-defined boundary in most areas, but deviated by several miles in some locations.

  In most locations, differences between the RASA boundary and the boundary of SRPAM1.1 are of little regional significance and do not represent a need to adjust location of the model boundary. Differences in two areas deserve discussion: 1) the extreme western end near King Hill, and 2) the area south of the Snake River near Twin Falls and Burley. These areas are discussed below.

On the extreme western end of the model domain (Figure 11), the RASA-defined boundary extends about 12 miles further west than the SRPAM1.1 model boundary. This area includes a length of the Snake River. Where aquifer discharge is negligible relative to the section immediately upstream. Covington and Weaver (1990) identify about 48 cfs of spring discharge emanating from about 20 springs along the Snake River in the reach beyond the western-most extent of the SRPAM1.1 model boundary and within the RASA-defined boundary of the eastern Snake River Plain. This represents about one percent of the total spring discharge in the reach from Milner Dam to King Hill, and does not provide sufficient justification for extending the boundaries of the SRPAM1.1 model to the west.

The RASA boundary extends south of the Snake River in the area near Twin Falls and Burley in contrast to the SRPAM1.1 model which is bounded by the Snake River in this area. Downstream from approximately Milner Dam (below Burley) the Snake River flows through a deeply incised canyon that likely separates aquifers on the north and south sides of the rivers. Ground-water communication beneath the river is considered to be negligible in this reach (Cosgrove and others, 1998). The Twin Falls area is hydrologically isolated by the canyon and presents no urgent need for appending to the SRPAM1.1 model. Further upstream, near Burley, the RASA boundary includes a portion of the Oakley Fan. In this reach, ground water may flow north beneath the Snake River (Young and Newton, 1989). This hydrologic connection implies that water use in the Oakley Fan can impact aquifer water levels within the Snake River Plain aquifer. The SRPAM1.1 model boundary assigns a fixed rate of underflow to the boundary, implying that ground water on the south side

of the boundary is in a state of equilibrium. Although the assumption of equilibrium is not entirely valid, simulation conditions are similar for many of the tributary valleys. At some time in the future, it may be desirable to develop a basin-wide model representing the Snake River Plain aquifer and the major tributaries. This would allow prediction of impacts on the Snake River from scenarios incorporating changes in water management in both the plain and in tributary valleys.

- Aquifer and river characteristics near the Snake River have a significant influence on model results. Field studies and data analyses should be initiated to learn more about the interaction between the aquifer and the river. The results of these investigations would enable improvements to the conceptual model and to the numerical model, particularly in areas such as riverbed conductance and river gains and losses.
- The model is two-dimensional and not capable of representing vertical flow in areas of significant vertical hydraulic gradient. Vertical flow may be significant in areas such as the Henrys Fork and Rigby Fan, the Mud Lake area, the American Falls area, the Rupert area, and near the Milner to King Hill reach of the Snake River. A three-dimensional model may be warranted in these areas, but development of a valid model will require substantial effort and data.
- The model has been calibrated to limited changes in aquifer water level over a one-year period. An improved estimate of the distribution of aquifer properties could be developed from long-term calibration. The long-term calibration should include periods in which significant changes occurred in aquifer recharge, discharge and

water levels. Pre-development to current year (approximately 100 years) or the 1950s to current year may be appropriate calibration periods.

- Expansion of the model domain to include the Henrys/South Forks of the Snake River changed the original model water budget for the calibration year. Part of a re-calibration effort should include water budget refinement and calibration of model parameters to match the revised water budget.
- Other limitations exist relative to current knowledge of aquifer bottom, confined and unconfined conditions, non-laminar flow, recharge and discharge distribution, and other factors.

RECOMMENDATIONS FOR FUTURE WORK

This project represents one step in a series of efforts to continually improve and upgrade the Snake River Plain Aquifer Model. The conversion of the model to use the MODFLOW code has opened more possibilities for model enhancements. Some suggested improvements in the Snake River Plain aquifer modeling process are described below. The order of the items does not imply importance or priority.

1. Evaluation of spring discharge and the relation to water levels.

   Springs in the Kimberly to King Hill and Blackfoot to Neeley segments of the Snake River are of great significance to water users and exert a major control on aquifer simulations. Therefore, the ability to simulate the response of spring discharge in these reaches to changes in aquifer recharge or discharge is critical. Our understanding of how spring discharges respond to changes in aquifer water levels is inadequate. Springs at different elevations may respond to greatly different degrees to aquifer pumping. The treatment of this mechanism in the model is greatly oversimplified. Field investigations should be initiated to help further our understanding of this vital part of the hydrologic system.

2. Develop an improved method for aquifer recharge accounting.

   Net recharge to the Snake River Plain model must be input for every grid cell and stress period. Recharge is currently determined as the net of many inputs representing irrigation diversions and pumping, canal seepage, precipitation, evapotranspiration, and underflow. SRPAM currently relies on a Fortran program to perform the necessary calculations and determine net recharge. The program logic is valid; however, improved methods are available through the use of geographic

information systems and databases. Conversion to new methods should allow for cataloging and documenting all of the basic data that is used to generate model input data sets. A systematic method can improve quality control procedures and reduce time investments in future work.

3. Changes to the Snake River Plain Aquifer Model (SRPAM).

There are several changes that can be made to the SRPAM model to make it more representative of the real system. Those changes include:

a) Representation of all reaches of the Snake River as river cells in MODFLOW. This is especially important in reaches such as the Shelley to Blackfoot reach where Kjelstrom (1995) indicates the river may be hydraulically connected with the aquifer.

b) Verification, and possibly calibration, of the model to the time period from pre-development to current time. Model calibration should be performed over the widest possible ranges of stress. Such calibration provides greater confidence in model results, especially when model predictions are within the range of stress from recharge and discharge to which the model was calibrated. This calibration should include inverse modeling techniques to help understand uncertainties and guide future data collection.

c) Conversion of the model inter-block transmissivity averaging scheme from the logarithmic mean to the harmonic mean. This conversion would make the model compatible with a wider range of user interfaces. As time progresses, however, the user interfaces are

developing the capability to support the logarithmic mean and this need diminishes. Changing the averaging technique would probably require model re-calibration.

d) Inverting the rows in the existing SRPAM grid. Some user interfaces are not compatible with the bottom-up row numbering used in the SRPAM grid. Converting to the more widely used top-down row numbering will increase compatibility. This need will also diminish as user interfaces become more flexible.

e) Expansion of the model domain to include the area south of the Snake River. Ground water in the Twin Falls area is probably hydrologically separated from the rest of the Snake River Plain aquifer by the deeply incised Snake River canyon. The area south of the river is, however, the largest single tract of irrigated land in Idaho, and has an impact on flows and quality of the Snake River. Evaluations of basin-wide changes in agriculture practices, and the potential impacts on the Snake River, must include the Twin Falls tract. Inclusion of this area in the ground water model may enhance use of the model for system planning.

f) Area-specific refinements in the model. The conceptual and numerical model may be improved in specific areas through more detailed investigations. These investigations should focus on areas of greatest uncertainty in aquifer characteristics and in areas of greatest interest.

These efforts will probably result in a refinement of the model grid and layers in the selected areas.

Modeling of an aquifer system should be treated as a continuous and ongoing process, with the door always left open to make improvements. The above recommendations are provided as ideas to fuel the process of continued model evolution.

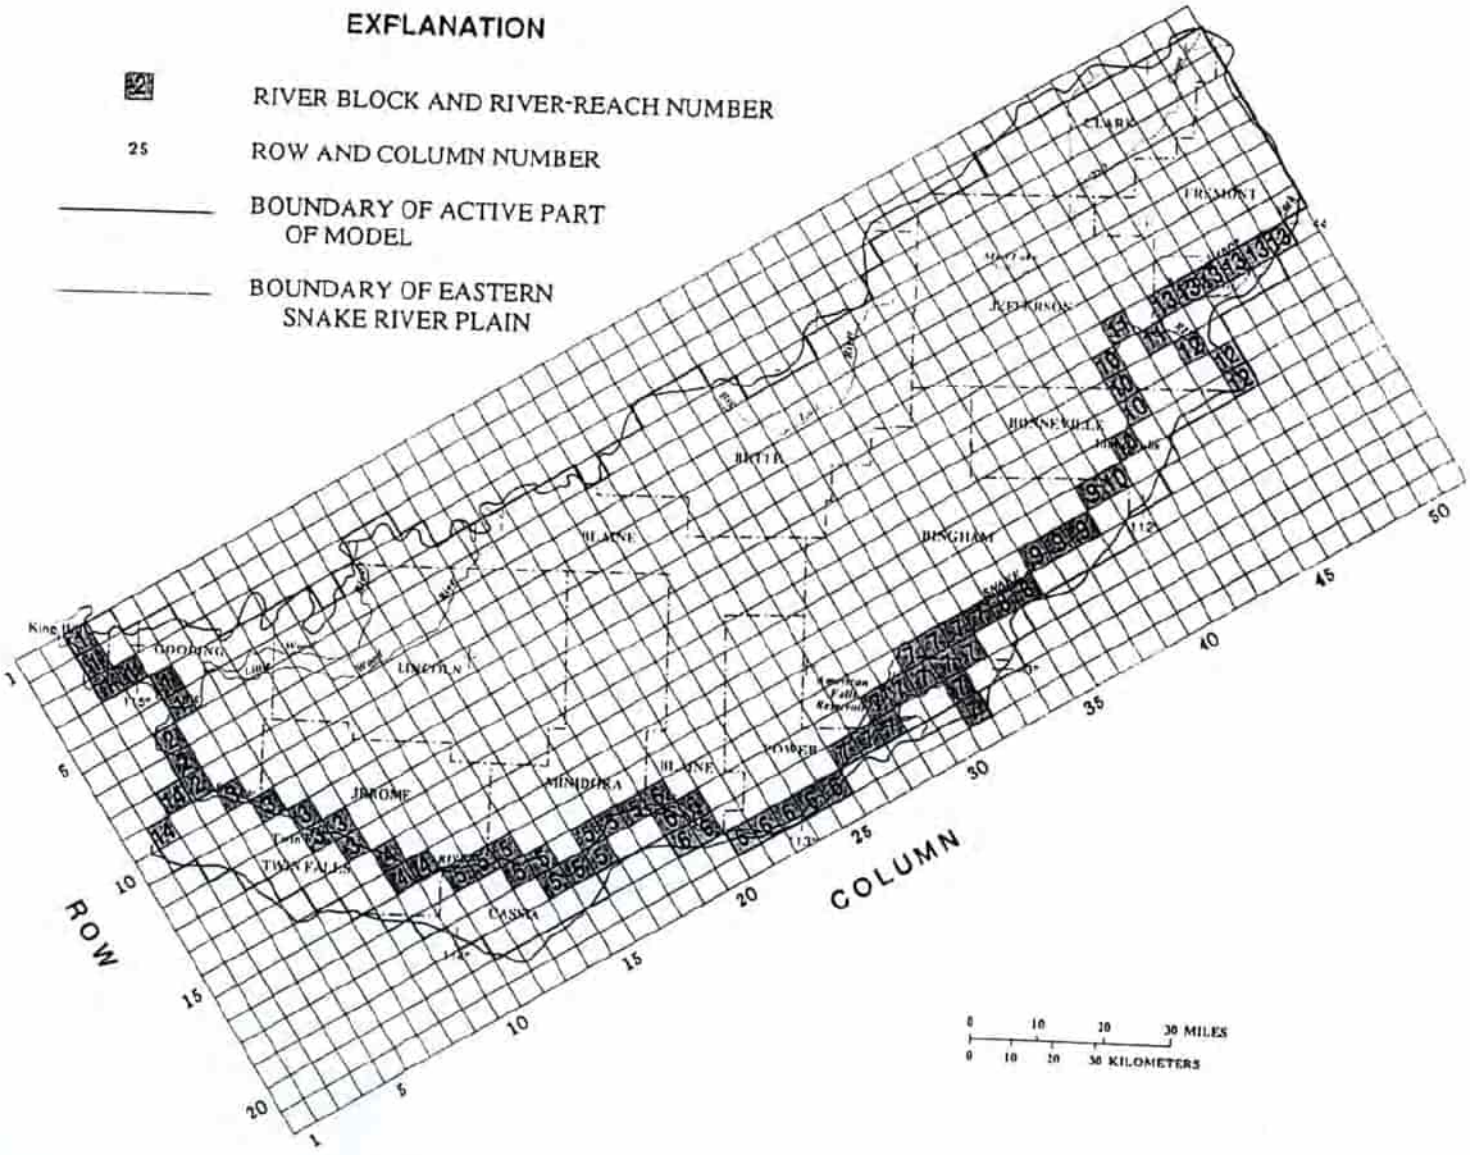
APPENDIX

This appendix provides a comparison of the SRPAM1.1 model with the USGS Snake River Plain Model (Garabedian, 1992). This comparison is provided to enable the reader to compare how two very similar models of the same region represent the physical characteristics of the area being modeled. The models were designed and implemented by different authors. The model boundaries are compared. Comparisons of physical properties such as transmissivity and specific yields are provided. A comparison is made of tributary underflow and distribution of aquifer recharge for the same water year. River representation in the two models also is discussed.

The reader should keep in mind that many of the decisions on SRPAM model design and generation of input data for the SRPAM model were made in the early 1970s. Evolution of the model since its development has not been fully documented, so the rationale behind many of the model assumptions is unknown. The following comparison is provided as a general guideline to the reader, for the purpose of demonstrating that two numerical models developed with different resources, by different modelers and at different times actually produce very comparable results.

COMPARISON OF MODEL BOUNDARIES FOR SRPAM1.1 VERSUS THE USGS SNAKE RIVER PLAIN MODEL

Both SRPAM1.1 and the USGS Snake River Plain Model generally conform to the RASA-defined boundaries of the Snake River Plain aquifer. SRPAM1.1 follows the RASA-defined boundary in most areas, but deviates by several miles in the extreme



northeast near Ashton, Idaho and in the extreme southwest near King Hill, Idaho. Figure A1 (from Garabedian, 1992) shows the conformance of the USGS model to the RASA-defined aquifer boundary. Figure 11 shows the SRPAM1.1 grid and the conformance to the RASA-defined boundary of the aquifer.

In most locations, differences between the RASA boundary and the boundary of SRPAM1.1 are of little regional significance. Differences in two areas, the extreme western end near King Hill and the area south of the Snake River near Twin Falls and Burley are significant and are discussed in the main body of this report.

The USGS transient model is a three layer, three-dimensional model, versus the one layer, two-dimensional SRPAM1.1. The USGS model contains 21 rows and 51 columns compared with the 48 rows and 65 columns of SRPAM1.1. The USGS model cells are 4 miles square versus 3.1 miles square for the SRPAM1.1 model cells. The SRPAM1.1 grid is oriented approximately north-south/east-west; the USGS grid is oriented southwest-northeast more parallel to the axis of the Snake River Plain. Approximately the same hydrologic features are represented in both models. For more information concerning the USGS model grid, the reader is referred to Garabedian (1992).

COMPARISON OF TRIBUTARY UNDERFLOW FOR SRPAM1.1 VERSUS THE USGS SNAKE RIVER PLAIN MODEL

SRPAM1.1 and USGS model underflow estimates are very similar for many tributaries but differ greatly in some areas. Table A1 lists the estimated tributary

Finite-difference grid, river blocks, and river-reach numbers used for three-dimensional model.

Figure A1. USGS Model Grid (from Garabedian, 1992).

[3] Garabedian (1992) specified reaches that may be included in other reaches of IDWR (1997), these do not include tributaries to the south side of the Snake River near Twin Falls.

underflow values for SRPAM1.1 and the USGS model. The largest difference in tributary underflow values is for the Big Lost River valley. The difference may be partially attributed to differences in boundary locations. Additionally, tributary underflow values are very difficult to estimate and are subject to great error.

COMPARISON OF MODELING OF RIVER REACHES FOR SRPAM1.1 VERSUS THE USGS SNAKE RIVER PLAIN MODEL

River reaches are modeled somewhat differently in the two models. As mentioned in the main body of this report, some of the reaches of the Snake River are modeled in SRPAM1.1 as head-dependent river reaches using the MODFLOW River package and other reaches are modeled as specified seepage reaches. All of the head-dependent reaches in the original, non-extended portion of SRPAM1.1 are modeled using an extremely high river conductance and arbitrarily small riverbed bottom elevation. This creates conditions identical to the earlier model version where flow is controlled by hydraulic conductivity of the river cell. In the USGS Snake River Plain Model, all of the cells representing Snake River reaches are modeled as head-dependent reaches using the MODFLOW River package, however, some of the reaches may be perched. Table A2 shows a comparison of river reaches on a reach by reach basis for the two models. River segment gains and losses were compared between the two models. Because the river segments from the Lewisville gage to the At Blackfoot gage are modeled in SRPAM1.1 as specified flux cells, and the same reach is represented as head-dependent river cells in the USGS model, a comparison of river gains and losses in these cells is not valid. Table

COMPARISON OF RECHARGE/DISCHARGE FOR SRPAM1.1 VERSUS THE USGS SNAKE RIVER PLAIN MODEL

Head-independent recharge and discharge were compared for the SRPAM1.1 model versus the USGS Snake River Plain Model. The USGS model cells were aggregated into 40 zones, presented by Garabedian (1992), for the purpose of data presentation. The same zones were translated to the SRPAM1.1 model grid. Net recharge within each zone for each model was calculated, with some assumptions:

1. Recharge was not compared in zones where the model boundaries do not coincide (the King Hill, Twin Falls and Oakley Fan areas).
2. The difference in handling of the Snake River between the two models made comparison of zones with modeled river reaches difficult. Some reaches modeled as head-dependent in the USGS model are represented as specified seepage in SRPAM1.1. All zones are included in the comparison, however for zones containing river reaches the comparison may be less valid.
3. Grid orientation and spacing are unequal between the two models—therefore zone boundaries are inexact when translated to the SRPAM1.1 grid and comparisons are only approximate.
4. The USGS model uses both the Recharge and the Well package to input recharge. Recharge from these two packages was summed for the comparison with SRPAM1.1.

Table A3. Comparison of Simulated River Gains and Losses in SRPAM1.1 versus the USGS Model.

River Segment	SRPAM1.1 Simulated River Gain or Loss (-) cfs	USGS Model Simulated River Gain or Loss (-) cfs	Measured River Gain or Loss (-)[1] cfs
Henrys Fork, Ashton To Rexburg	130	30	120
South Fork, Heise to Lorenzo	-130	-180	-150
Snake River, Lorenzo to Lewisville	270	40	290
Snake River, Near Blackfoot to Neeley	2640	2640	2620
Snake River, Neeley to Minidoka	-110	20	180
Snake River, Milner to King Hill	5874	4030	6540

[1] from Garabedian (1992)

Figure A2 shows the USGS model zones overlain on the SRPAM1.1 model grid. Figure A3 shows both the USGS model recharge and the SRPAM1.1 recharge (repeated from Figure 19) mapped to the SRPAM1.1. Figure A3 was generated using the average annual recharge applied in the transient USGS model for the 1976-1980 time period and the 1980-81 calibration data set for the SRPAM1.1 model. Comparison of the two maps in Figure A3 shows that recharge for the two models is almost identically distributed, despite being derived using very different methods.

Figure A4 shows a scatter plot of recharge aggregated by USGS model zone for the two models. The line in Figure A4 is a line of equal recharge. Data points falling on the line represent zones where the USGS model recharge equals the SRPAM1.1 recharge. Data points falling to the right of the line represent zones where the USGS recharge is higher. Data points falling above the line represent zones where the SRPAM1.1 recharge is higher. With the exception of one zone (zone 17), the aggregated recharge for each zone is reasonably well centered around the line of equal recharge. Zone 17 represents the Heise area and includes many river cells, which may explain the difference in recharge between the two models. Table A4 lists the summed recharge by zone for the two models.

COMPARISON OF AQUIFER PROPERTIES FOR SRPAM1.1 VERSUS THE USGS SNAKE RIVER PLAIN MODEL

Transmissivities and specific yields were compared between SRPAM1.1 and the USGS Snake River Plain Model (Garabedian, 1992). Transmissivities for the unconfined layer in the USGS model were calculated by multiplying hydraulic conductivities by layer thickness. The transmissivities were then summed for the three transient USGS model layers. Figure A5 shows the areal distribution of transmissivities for the USGS model and for SRPAM1.1 (repeated from Figure 20). A comparison of the two maps in Figure A5 shows that transmissivities in the two models are similarly distributed across the Snake River Plain and are of similar magnitude. Both models were calibrated using measured water levels for the 1980-1981 time period, but using different calibration methods, yet the distribution of transmissivities is similar between the two models.

A zone-based comparison of transmissivity also is useful. Transmissivities were calculated and then averaged within the zones shown in Figure A2. Similarly, the hydraulic conductivities for the single, unconfined layer of SRPAM1.1 were multiplied by aquifer thickness to obtain transmissivities and averaged within each zone. Figure A6 shows a log-scale scatter plot of transmissivities for the USGS model versus SRPAM1.1. The diagonal line in Figure A6 represents a line of equal transmissivity (i.e. a data point falling on the line indicates that for that particular zone, the USGS model transmissivity and the SRPAM1.1 transmissivity are the same). The approximately equal distribution of points above and below the line of equal transmissivity indicates that neither model

EXHIBIT "505"
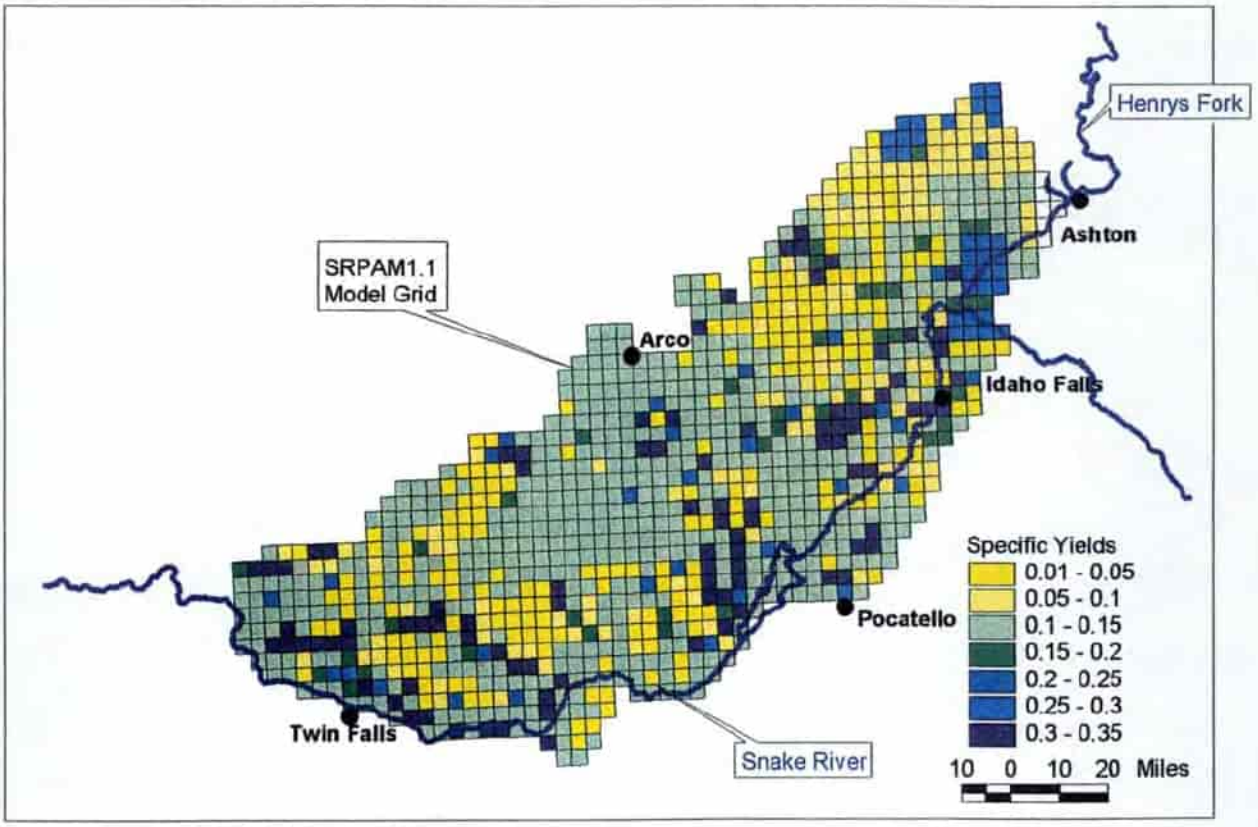
Page No. 90 of 101



is particularly biased towards low or high transmissivities. Figure A6 does, however, show a great variation in the transmissivity values within each model, an expected condition for a regional model of a heterogeneous system such as the Snake River Plain aquifer.

Similarly, specific yields were compared for the two models. Figure A7 shows the areal distribution of specific yield values for the USGS and the SRPAM1.1 (repeated from Figure 21) models. Specific yields for both models were averaged for the 40 zones previously described. The specific yield for the upper-most, unconfined layer of the USGS model was compared with the specific yield for the SRPAM1.1. Figure A8 shows a scatter plot of the USGS model specific yields versus the SRPAM1.1 specific yields. The diagonal line represents the line of equal specific yield (i.e. any data point falling on the line indicates that for that particular zone, the USGS specific yield equals the SRPAM1.1 specific yield). The number of data points falling above the line indicates a bias towards higher specific yields in the SRPAM1.1 model. On the average, the specific yields in the SRPAM1.1 model are approximately 50% higher than the specific yields in the USGS model. Higher specific yields will cause the SRPAM1.1 model to store or release more water per unit change in aquifer water level. Figure A9 shows a histogram of specific yield values for the USGS Model. This figure is provided for comparison with Figure 22.

Comparison of these two figures also indicates a bias towards higher specific yields in the SRPAM1.1 model. Table A5 shows the average transmissivities and specific yields for the forty zones for both the SRPAM1.1 and the USGS models.

CONCLUSION

Comparison of the SRPAM1.1 model parameters with the USGS Snake River Plain Model parameters demonstrates some degree of variability in modeling assumptions and calibrated values. However, comparison of the two models shows a high degree of similarity in the distribution of recharge, the calculated river gains and losses and the distribution of transmissivities, three properties which exert great control on modeling results. This high degree of similarity provides confidence that each model reflects a reasonably accurate representation of conditions within the modeled area. Further work should be done to understand what effect the differences exert on predictive results.

Abstract

The development of ground-water and surface-water irrigation on the eastern Snake River Plain has necessitated conjunctive management of the ground and surface water resources. To facilitate this management approach, the Idaho Department of Water Resources (IDWR) has placed a strong emphasis on the development, use and refinement of scientific tools which help quantify the impacts of changing water use practices on ground water and surface water supplies on the eastern Snake River Plain. Recognizing the importance of the ground-water model as a water management tool, the IDWR, the State Legislature and the water user community agreed to embark on a model reformulation process.

Model reformulation was funded as a joint effort between the State of Idaho, Idaho Power, the U.S. Bureau of Reclamation and the U.S. Geological Survey. The reformulation was overseen by the Eastern Snake Hydrologic Modeling Committee (ESHMC), a collection of scientists and engineers representing the above-identified agencies and private water user groups. The actual modeling was accomplished by the Idaho Water Resources Research Institute (IWRRI) at the University of Idaho. Major design alternatives were presented to ESHMC members for discussion and guidance. The model development was accomplished in an open environment, with acceptance of design input from all committee members, in an attempt to allay concerns regarding technical bias.

The technical effort was initiated in 1999 and involved data collection for a 22-year calibration period (Spring, 1980 through Spring, 2002), establishing a new model grid and boundary conditions and an exhaustive calibration of the new model. The 22-

year calibration period was broken into 44 6-month stress periods. The calibration was accomplished using version 9.0 of PEST (Doherty, 2005), a non-linear parameter estimation program for data interpretation, model calibration and predictive analysis. The model was calibrated to approximately 11,000 aquifer water level and river gain/loss observations. The resulting model, the Enhanced Snake River Plain Aquifer Model (ESPAM), is a single layer, confined model with 104 rows and 209 columns. Each model grid cell is 1 mile x 1 mile. The model contains 11,451 active cells.

This report documents the enhancement (i.e. design and calibration) of the ESPAM. As design decisions were made during the life of the project, a series of thirty-five reports called Design Documents were written and circulated among ESHMC members for review and comment. The Design Documents contain further details including design alternatives which were considered and the rationale for selecting a specific design option. This report details the accounting of recharge and discharge for the 22-year calibration period, the technical tools used to develop the model, the observations used for model calibration and comparison of the model-predicted aquifer water levels and river gains with observed data. The report cites the various Design Documents for the reader who is interested in more detail.

As with any model of a complex physical system the ESPAM has limitations and uncertainties. The ESPAM is a regional-scale model and is best applied for regional-scale predictions. Additionally, some of the water budget elements and measured observations are known with greater certainty than others. Further discussion about model limitations can be found in the section entitled Model Limitations.

The ESPAM will be used to quantify the impacts of ground-water use on surface water resources. No attempt is made in this report to address the topic of injury to senior water rights.

Introduction

Background and Study Objectives

Ground water and surface water are highly interconnected on the eastern Snake River Plain. This report documents the design, development and calibration of the Enhanced Snake Plain Aquifer Model (ESPAM). The ESPAM will be used by the Idaho Department of Water Resources to estimate impacts between ground water use and surface water resources to support water management decisions.

This project was initiated as a joint effort overseen by groups of eastern Snake River Plain (ESRP) water interests. The study was funded jointly by the State of Idaho, Idaho Power, the U.S. Bureau of Reclamation, with in-kind services from the U.S. Geological Survey (USGS). Technical oversight and input from representatives of these entities andd water user groups were incorporated in the model development to create the best possible technical tool for management of ground-water resources on the eastern Snake River Plain and to which all involved parties could agree is an unbiased representation of the complex aquifer system. The process, which was established for allowing oversight and technical input from the interested parties, is described in a later section.

The ESPAM project had several other objectives in addition to creating a model which all interested parties could agree to and support. These objectives are: a) to create a numerical ground-water model of the eastern Snake River Plain aquifer which is calibrated to a sufficient time period to represent a wide range of aquifer stresses, b) to improve the model representation of river/aquifer interaction, c) to fully document the

new model including major design decisions and data, and d) to create the model using state of the art model development methods.

Project Scope

The scope of this project was limited to the reformulation and re-calibration of the ground-water model used for water management on the eastern Snake River Plain. This entails the accurate accounting of aquifer recharge and discharge for the modeled period, an accurate assessment of water use on the eastern Snake River Plain, and creation and calibration of a numerical model to represent the Snake River Plain aquifer. The scope of the project was limited to model creation and calibration and did not entail generation of water management scenarios.

The Role of the Eastern Snake Hydrologic Modeling Committee

The ESPAM was created with extensive review and input from the Eastern Snake Hydrologic Modeling Committee (ESHMC) during the period from 1999 through June, 2005. The ESHMC is comprised of professionals working on water issues on the eastern Snake River Plain. Regular members include agency representatives (Idaho Department of Water Resources, U.S. Bureau of Reclamation, U.S. Geological Survey, U.S. Fish and Wildlife Service), industry representatives (Idaho Power), researchers (University of Idaho, Idaho Water Resources Research Institute) and private consultants representing water users on the eastern Snake River Plain. The ESHMC was formed in 1998 and was a follow-on to the previous Idaho Technical Committee on Hydrology (ITCH) which had a similar function. The ESHMC was originally formed to allow researchers and water users a forum for discussing water issues and research on the eastern Snake River Plain and is chaired by the Idaho Department of Water Resources.

Shortly after its formation, the ESHMC was tasked to identify the most critical research needs on the eastern Snake River Plain. The reformulation of the ground-water model was a high priority identified by the ESHMC. Model reformulation was funded jointly by the State of Idaho, Idaho Power and the U.S. Bureau of Reclamation, with in-kind services provided by the U.S. Geological Survey. Model development was contracted by IDWR to IWRRI. Program management for the model reformulation was provided by IDWR. However, realizing the contentious nature of water disputes on the eastern Snake River Plain and, in an effort to temper future disagreement, IDWR elected to have the model design, construction and calibration overseen by the ESHMC. IDWR's goal was to provide insight and input into the model design so that all parties could attest to the facts that a) the model was created with as little bias as possible and b) the model was as accurate a representation of the physical system as possible, given the available data. IDWR further stated the goal that future water disputes on the eastern Snake River Plain should be focused on policy and not on the science. It was understood that not every decision would attain complete agreement from all members of the ESHMC.

IWRRI held approximately quarterly meetings to present project status and proposed design choices to the ESHMC. The design choices were documented in a series of technical reports that are called Design Documents. The Design Documents were distributed to ESHMC members in draft form prior to all design review meetings. During the design reviews, the ESHMC members received presentations of various design options. These options would often be discussed at length. Once either consensus (but not necessarily unanimous agreement) was reached or there was no further

discussion, the final design decision was documented in a final version of the relevant Design Document. Many fundamental design decisions were modified specifically in response to ESHMC guidance. Realizing that the group was being presented with an extraordinary volume of information and detail during the design reviews, the ESHMC members were encouraged to provide written comments on specific Design Documents or on specific design issues as well as oral comments during meetings.

If, in the course of model development or calibration, the technical team determined that a design decision needed to be changed or required more extensive Committee review, either a memorandum or a revised version of the Design Document was distributed to the ESHMC. At every juncture, the ESHMC committee members were kept apprised of model design options and decisions.

Recognizing that multiple (often disparate) viewpoints were represented at ESHMC meetings, it was understood that not all design decisions could be made with unanimous agreement. All major design decisions, however, were discussed at length and consensus on the design approach was reached among the present parties. Throughout this report, major design decisions made by the ESHMC members are noted. The authors recognize that this is an extraordinary approach for ground-water model documentation; however, the authors feel that the method of model development, including and soliciting input from interested parties from the very beginning of model design, was a unique approach aimed at gaining consensus on a potentially contentious model.

ESPAM Version

During the preparation of this final project report, some data entry errors were discovered in the original model calibration, requiring model re-calibration. The data entry errors were centered around the calibration targets used for the river reaches in the upper Snake River. The most significant data entry errors were that the measured irrigation return flow percentages had not been integrated into the model calibration targets and there was a mismatch in reach integration between the model-predicted and observed values for the Shelley to Near Blackfoot and Near Blackfoot to Neeley reaches. These data entry errors were corrected and the model was re-calibrated in May, 2005, resulting in the release of ESPAM Version 1.1, which is described in this report. These data entry errors did not significantly affect results of the model simulation.

Study Area Description

The Snake River Plain extends in an arcuate shape across most of southern Idaho and into eastern Oregon. The plain is divided into eastern and western regions based primarily on ground-water hydrology. The eastern Snake River Plain is the focus of this report and entails an area of about 10,000 square miles extending from Ashton, Idaho in the northeast, southwest to King Hill, Idaho (Figure 1). The boundaries of the plain, shown in Figure 1, were originally defined by the U.S. Geological Survey's Regional Aquifer- System Analysis (RASA) program (Lindholm, 1993) and were modified for this study (see Geographic Boundary Conditions section). The model boundary shown in Figure 1 is the modified boundary used for this study. Elevation of the eastern plain varies from about 2600 feet above sea level in the southwest to over 5000 feet in the northeast.

Population within the plain is generally sparse, with most of the population residing along the eastern and southern margins of the plain in an agriculturally productive band near the Snake River. Much of the remainder of the plain is federal land managed primarily by the U.S. Bureau of Land Management. Extensive portions of the plain are covered by rugged basalt outcroppings that include the Craters of the Moon National Monument.

The Snake River Plain enjoys an arid to semi-arid temperate climate. Precipitation ranges from about 8 to 14 inches per year, falling predominantly in the colder months. Irrigation is required for agricultural production. The crops grown vary with location; the major crops throughout the plain include potatoes, wheat, barley, alfalfa, and sugar beets. Dry edible beans, corn and peas are grown in the southwestern part of the valley.

Irrigation on the eastern Snake River Plain began in the late 1800s using water from the Snake River and its tributaries. Garabedian (1992) describes changes in surface-water and ground-water irrigated areas on the eastern Snake River Plain that are shown graphically in Figure 2. Acreage irrigated by surface water has been declining since the mid-1940s. Since the onset of ground-water irrigation in the 1950s, the number of acres irrigated by ground water increased steadily until the early 1990s.

Irrigation practices are continually changing in response to technology and economic factors. Furrow, flood, and sub-irrigation were the dominant methods of water application into the second half of the twentieth century. In the 1980s and 1990s sprinkler systems have commonly replaced surface application methods, with a resulting decrease in the amount of water diverted per acre of agricultural land.

Significant legal developments in the 1990s have dramatically affected water use on the Snake River Plain. A basin-wide adjudication of water rights was initiated in 1987 (Idaho Water Resources Board, 1996). The Idaho State legislature enacted legislation affecting the adjudication, including recognition of enlargements in irrigated acreage that occurred before 1987. A moratorium on expansion of irrigated acreage has been in effect for the Snake River Basin since 1992. The moratorium includes both surface and ground water irrigated lands within the basin (Idaho Water Resource Board, 1996). Conjunctive management rules were adopted by the Idaho Department of Water Resources (IDWR) in 1994, essentially linking administration of ground- and surface-water rights. Water measurement districts were established in 1996 to provide records of ground-water pumpage for irrigation. Managed recharge of the Snake River Plain aquifer has also been supported by the Idaho legislature. Estimates for managed recharge, which has occurred at various locations through existing irrigation facilities, are listed in Table 1.

The onset of drought conditions in 2000 caused multiple legal actions to be initiated accelerating the conjunctive administration of surface- and ground-water resources. It was widely agreed that the old numerical model of the eastern Snake River Plain was not sufficiently documented to support conjunctive management decisions.

Model History

Numerical ground-water flow models of the Snake River Plain aquifer have been developed and applied by state and federal agencies, universities, and private interests. The models vary in purpose, extent, and the computer code employed. The first numerical model of the aquifer was developed by the University of Idaho for IDWR and

the U.S. Bureau of Reclamation (deSonneville, 1974). The original IDWR/UI model has undergone multiple revisions and improvements, described below.

The finite-difference model code developed by the University of Idaho and evolved by the University and the IDWR will be referred to as the IDWR/UI Ground Water Flow Model Code. The application of this code to the Snake River Plain aquifer will be referred to as the IDWR/UI Ground Water Flow Model, following the convention established by the IDWR (IDWR, 1997a). The IDWR has applied various versions of this model as a planning and management tool for over two decades.

In the early 1980s, the IDWR/UI Ground Water Flow Model was re-calibrated to 1980-1981 conditions. This re-calibration was able to capitalize on the extensive data collection effort which the USGS did in support of the Regional Aquifer-System Analysis (RASA) study of the Snake River plain during that period. In the early 1980s, the USGS also created a model of the eastern Snake River Plain aquifer for scientific investigations (Garabedian, 1992).

In 1999, the IDWR/UI Ground Water Flow Model was converted to use one of the most widely used and accepted ground-water modeling codes, MODFLOW (McDonald and Harbaugh, 1988). The conversion to MODFLOW was not intended to create a new model, but to develop an equivalent model using a different code. Model representation of physical properties such as aquifer transmissivity, storage and streambed conductance were preserved in this conversion of the IDWR/UI Ground Water Flow Model to the MODFLOW code. The 1999 MODFLOW application to the Snake River Plain aquifer will be referred to as the Snake River Plain Aquifer Model (SRPAM), with the most recent version being SRPAM1.1. There were several benefits gained from

conversion to the MODFLOW code including: a) the MODFLOW code is accepted as an industry standard, b) MODFLOW includes algorithms that simulate physical processes and have been verified against analytical solutions, c) MODFLOW is more familiar to a wider group of scientists and engineers, d) numerous user interfaces have been developed for MODFLOW, e) MODFLOW capabilities are continuously increasing, f) MODFLOW has a significant capability for treating more advanced features such as three-dimensional flow and variable grid spacing, and g) the MODFLOW code is well documented.

In addition to conversion of the IDWR/UI Ground Water Flow Model to the MODFLOW code, the model was modified to improve model representation of the physical system. This was achieved primarily by expansion of the model domain to include segments of the Snake River and tributaries in the northeast portion of the plain that were not previously simulated. Additionally, model documentation was significantly enhanced (Cosgrove and others, 1999; Johnson and others, 1999).

With the potential for rising conflict between surface water and ground water users on the eastern Snake River Plain, in 2000, IDWR embarked upon a full reformulation and re-calibration of the ground water model. This effort resulted in the model which is documented in this report. The resulting model is called the Enhanced Snake Plain Aquifer Model (ESPAM).

Hydrogeology

Geologic Framework

The surface of the Snake River Plain consists primarily of volcanic rocks, which, in most areas, are covered by a veneer of windblown or fluvial sediments. Sediment deposits overlying the basalt vary in thickness from zero to tens of feet. Exposed

volcanic rocks are predominantly basalt, which in places such as the Craters of the Moon National Monument, cover expansive areas.

The eastern Snake River Plain is composed of a series of relatively thin basalt flows and interbedded sediments. Flows range in thickness from a few feet to tens of feet. Welhan and Funderberg (1997) report median flow thickness near the Idaho National Laboratory ranging from about 7 to 25 feet. Individual flows typically have a rubble or clinker zone at the top and bottom with a more massive interior containing fewer vesicles. Vertical fractures in the flow interiors form columnar basalt in some locations (Garabedian, 1992). Individual basalt flows generally are not extensive (Welhan and Funderberg, 1997). The collective thickness of basalt flows of the eastern Snake River Plain is estimated to exceed several thousand feet in places (Whitehead, 1986). More detailed descriptions of the geology of the eastern Snake River Plain are provided by Anderson (1991), Whitehead (1986), and Kuntz and others (1992).

The eastern plain is bounded structurally by faulting on the northwest and downwarping and faulting on the southeast (Whitehead, 1986). The plain is bounded by Yellowstone Group rhyolite in the northeast and Idavada volcanics in the southwest. Granitic rocks of the Idaho batholith, along with pre-Cretaceous sedimentary and metamorphic rocks, border the plain to the northwest (Garabedian, 1992).

Surface-Water Hydrology

The Snake River passes along the southern margin of the eastern Snake River Plain and is the exclusive surface water discharge mechanism for the eastern plain. Ground water underflow from the eastern plain into the western plain is assumed to be minimal, due to the more extensive low hydraulic conductivity sedimentary deposits of

the western plain. Consequently, flow of the Snake River at King Hill is widely considered to be the equivalent of basin discharge, excluding evaporation. Annual discharge of the Snake River at King Hill is shown in Figure 3. The cumulative discharge line in Figure 3 shows little long-term change in slope. This indicates that despite significant changes in water use during the last several decades, there has been little change in basin outflow. A possible reason for the stability of the slope of the cumulative graph in Figure 3 is that human activities have apparently had a greater temporary impact on aquifer storage than on basin outflow.

The Snake River is intensively managed for irrigation and hydropower generation. The average annual flow, major inflows and diversions at different points within the system are illustrated by river width in Figure 4. The flow in the Snake River is noticeably depleted at Milner Dam where substantial diversions are made for irrigation. A gradual increase in river flow below Milner Dam is due largely to aquifer discharge in the form of springs emitting from the wall of the Snake River canyon. North of Idaho Falls, in the eastern part of the plain, the Henrys Fork (locally referred to as the North Fork) joins the Snake River, locally referred to as the South Fork, shortly downstream from Lorenzo, Idaho. The origin of the Henrys Fork is in the Island Park area to the northeast of the Snake River Plain. Headwaters of the Snake River (South Fork) are in Yellowstone Park in Wyoming. On average, flow of the Snake River at Lorenzo is about triple the flow of the Henrys Fork near Rexburg.

Several reservoirs have been constructed on the Snake River and its tributaries for the purposes of irrigation, flood control, hydropower generation, and recreation. In some years, spring snowmelt exceeds system storage capacity and irrigation demands and

water is spilled past Milner Dam. On average, about two million AF of water are discharged annually past Milner Dam (Figure 5).

Direct tributaries to the Snake River occur primarily from the east and south sides of the basin. Several streams along the northern margin disappear through seepage before flows can reach the Snake River (Figure 4). Only flows of the Big and Little Wood Rivers, Silver Creek (not shown in Figure 4, but tributary to the Big Wood River), and Camas Creek may eventually reach the Snake River from the northern margin of the plain. Other streams on the northern margin of the plain, such as the Big and Little Lost Rivers, contribute recharge to the Snake River Plain aquifer, but do not directly discharge to the Snake River.

An extensive network of irrigation canals provides water for approximately 1.0 million acres of surface-water irrigated land on the eastern Snake River Plain. Technical reports provide different estimates of surface water irrigated land due to: 1) differences in the area being evaluated, 2) difficulties discriminating between ground-water and surface-water irrigated land in some locations, and 3) the application of adjustments for non-productive lands (e.g. homesteads, roads, ditches) within an area that appears irrigated in satellite images. In 1980, the U.S. Geological Survey reported 2.1 million acres of irrigated land (both surface- and ground-water) on the eastern Snake River Plain (Garabedian, 1992) within the RASA aquifer boundary. For the current study, it was estimated that there are 1.0 million acres irrigated by surface water and 1.1 million acres irrigated by ground water, for a total of 2.1 million irrigated acres.

Irrigation diversions consume a large proportion of the flow of the Snake River during irrigation season. Diversions of surface water for irrigation in the eastern Snake

River Plain (including all tributaries) have diminished by about 20 percent from the nearly eight million AF/yr diverted in the early 1970s (IDWR, 1997a). Irrigation diversions both deplete and affect the timing of flows in the river, with some of the diverted water returning to the river as either surface or ground water return flows. In addition, surface water diverted for irrigation also has a major effect on recharge of the Snake River Plain aquifer as will be discussed in the following section.

Extensive ground water irrigation across the plain also impacts the surface water resources. Due to the interconnection between the aquifer and the river, water withdrawn from the aquifer to supply the approximately 1.1 million acres of ground-water irrigated land either diminishes aquifer discharge to the river or increases river losses to the aquifer.

Ground-Water Hydrology

The Snake River Plain aquifer underlies the eastern Snake River Plain. This highly productive aquifer is hosted in fractured basalts and interbedded sediments. The primary conduit for ground-water flow appears to be the highly permeable rubble zones that formed at the tops of the numerous basalt flows which comprise the Snake River Plain. Garabedian (1992) reports median specific capacity on a county basis for 176 wells across the eastern plain. The median values ranged from 4 to 950 gallons per minute per foot of drawdown, with the largest values occurring in counties near the center of the plain where Quaternary basalts are thickest. The lower values were found near the margins of the plain where Tertiary basalts and sediments predominate.

Although the collective thickness of the basalt flows may be in excess of several thousand feet in places, the active portion of the aquifer often is thought to be limited to

the upper several hundred feet of saturated thickness. Robertson (1974) states that "Although the real aquifer system is probably more than 1,000 feet thick, a thickness of 250 feet is used in this study based on the apparent layering effects of the aquifer." Based on the presence of low permeability sedimentary layers encountered in a well drilled on the Idaho National Laboratory, Mann (1986) suggests that the aquifer is 450-800 feet thick. Model studies by the U.S. Geological Survey (Garabedian, 1992) represent the aquifer as four layers with a collective thickness ranging from 500 to over 3,000 feet. Modeling by the IDWR and the University of Idaho (deSonneville, 1974; Newton, 1978; IDWR, 1997a; Cosgrove and others, 1999) represents the aquifer as a single layer ranging from 200 to 1,700 feet thick.

The Snake River Plain aquifer generally is considered unconfined; however, in some locations and under certain conditions the aquifer responds as a confined system. In some areas, low permeability lakebed sediments create local confining layers (Spinazola, 1994). The layered basalts and interbedded sediments also may produce conditions that appear locally confined, at least when subjected to short duration stress (Frederick and Johnson, 1996).

The Snake River Plain aquifer is recharged by irrigation percolation; canal, stream, and river losses; subsurface flow from tributary valleys; and precipitation directly on the plain. The aquifer discharges to the Snake River, springs along the Snake River and to ground-water pumping, primarily for irrigation. Figure 6 shows a conceptual model of recharge and discharge to the Snake River Plain aquifer. The relative magnitudes of the recharge and discharge components were evaluated by the USGS (Garabedian, 1992) and, more recently, for this study. Estimates from the USGS

represent conditions in 1980 for the entire Snake River Plain (Figure 7). Estimates from the current study represent an average of 1980 through 2001 conditions (Figure 8). The USGS estimates of water budget components include portions of the plain not included in the current estimate due to differences in model boundaries (model extent is discussed in a later section).

Incidental aquifer recharge from irrigation is a significant component of the water budget and has varied as irrigation practices have evolved. The 1980 water budget of the USGS (Garabedian, 1992), shown in Figure 7, shows that surface water irrigation contributes more than 50 percent of the total recharge to the aquifer. Historically, recharge from surface water irrigation increased as more land was brought into production up to the 1970s. Since the 1970s, a gradual conversion to sprinkler irrigation methods reduced the amount of incidental recharge from irrigation.

Natural discharge from the Snake River Plain aquifer is primarily to the Snake River along two reaches: Kimberly to King Hill, and Near Blackfoot to Neeley. These reaches are defined by gaging stations shown in Figure 1. Spring discharge has varied in response to changes in precipitation, irrigated acreage, and irrigation practices. Overall, discharge in the Kimberly to King Hill reach appears to have been impacted more than in the Near Blackfoot to Neeley reach (Figure 9), although the Near Blackfoot to Neeley reach shows more seasonal variation since approximately 1970. The effects of weather variation and irrigation recharge are apparent from the short-term variation of spring discharge. Maximum discharge occurs around October, near the end of the irrigation season. The seasonal variation in the Blackfoot to Neeley and Milner to King Hill

reaches is about 15 and 20 percent of the respective maximum reach gains (from interpretation of Kjelstrom, 1995a).

Historically, aquifer water levels and corresponding discharges to the Snake River rose significantly at the onset of surface water irrigation. This is particularly apparent in the historic discharge in the Milner to King Hill reach shown in Figure 9. Aquifer water levels peaked around 1950 and have been declining since that time. The declines are attributed to the onset of ground-water irrigation, more efficient surface water irrigation practices such as conversion to sprinkler irrigation and canal lining, and the recent seven years of drought. Historic discharge in the Near Blackfoot to Neeley reach shows a less dramatic response to historic changes in irrigation practices, however the reach does exhibit more dramatic seasonal variation since the 1950s.

Other reaches of the Snake River also are hydraulically connected to the aquifer. In these segments, the river may gain or lose water, depending on river stage and the water level in the aquifer. The Neeley to Minidoka reach both gains and loses water, with gains generally exceeding losses. Further upstream, between Heise and Lorenzo, the South Fork of the Snake River is a seasonally losing stream (Kjelstrom, 1995a). Average annual loss of this reach was 150 ft^3/sec in the 1980 water year. During that same period, the Lorenzo to Lewisville reach of the main stem of the Snake River and the lower Henrys Fork reach were estimated to have gained 290 and 120 ft^3/sec, respectively (Garabedian, 1992).

Contours of the potentiometric surface indicate that ground-water flow direction generally is parallel to the axis of the plain (Figure 10). Steep hydraulic gradients are apparent near the margins of the plain due to tributary valley inflow and lower

transmissivity relative to the center of the plain. Steep gradients also are apparent near the Kimberly to King Hill discharge area due to convergence of flow lines and probable aquifer thinning. Near the center of the plain and near Mud Lake, steeper gradients presumably result from decreased transmissivity due to the volcanic rift zone and thick sediment deposits, respectively. Garabedian (1992) used transmissivities ranging from $4x10^3$ to $1x10^7$ ft^2/day. The SRPAM model had transmissivities which ranged from $2x10^4$ to $5x10^6$ ft^2/day. These ranges of values are consistent with published values for fractured basalt.

Aquifer storage in the eastern Snake River Plain aquifer is reasonably high due to the highly fractured nature of the system. Garabedian (1992) used specific yield values ranging from .05 to .2 (unitless ratio). Specific yield values used in the SRPAM model were higher, ranging from .08 to .26. The specific yield values used by Garabedian and the SRPAM model are consistent with published specific yield values for fractured basalts in unconfined systems, although many of the SRPAM values are at the upper limits of published values.

Aquifer water levels have changed significantly over the past several decades in response to changes in irrigation and variations in weather. Figure 11 shows the water level changes on the eastern Snake River Plain for the period from spring, 1980 to spring, 2002. This change in water level corresponds approximately to the change in aquifer storage shown in Figure 8 (Figure 8 shows the change in storage up through 2001). During that period, water levels across the plain generally declined between 5 and 15 feet, with some areas experiencing declines as great as 20-25 feet. The greatest changes in water level appear in a band traversing the south-central portion of the plain. Figure

12 shows water level declines between spring, 2001 and spring, 2002, the last year of the period shown in Figure 11. The reader will note that water level declines shown in Figure 12 are almost half of the total decline in the 1980-2002 period, reflecting a rapid aquifer response to the drought conditions of the year 2001-2002. This suggests that under long-term, average conditions (1980-2001), water use on the eastern Snake River Plain was reasonably in balance with use slightly exceeding supply. The rapid decline in the 2001-2002 year indicates that water level declines occur rapidly under drought conditions. This general decline in water level is consistent with observed declines in aquifer discharge to the Snake River.

Model Description

Governing Equations and Model Code

The mathematical equations governing unconfined flow are non-linear due to the fact that saturated thickness and, therefore, transmissivity, change with time. In confined systems, saturated thickness is constant, therefore the mathematical representation is linear.

The ESPAM is a confined representation of the eastern Snake River Plain aquifer. This decision was made by the ESHM Committee and was consistent with field observations of the propagation of pumping impacts through the aquifer (Frederick and Johnson, 1996). Additionally, the deep saturated thickness (Whitehead, 1986) supports the representation of a generally unconfined aquifer as confined since drawdowns in the highly transmissive aquifer will be less than 10% of total saturated thickness in most management applications (Anderson and Woessner, 1992). The confined representation of the eastern Snake River Plain aquifer allows a more stable numerical simulation of the

aquifer during automated model calibration. ESPAM Design Document DDM-019 discusses the confined representation of the ESPAM. The thickness of the aquifer is discussed further in the section on Geographic Boundary Conditions.

The general equation governing confined, steady state, anisotripic, heterogeneous flow in two dimensions is:

$$\frac{\partial}{\partial \mathrm{x}}\left(K_{xx}\frac{\partial h}{\partial x}\right)+\frac{\partial}{\partial \mathrm{y}}\left(K_{yy}\frac{\partial h}{\partial y}\right)=0 \qquad \text{(Eq. 1)}$$

where:

K_{xx} is hydraulic conductivity in the x-dimension (ft/d)

K_{yy} is hydraulic conductivity in the y-dimension (ft/d)

h is aquifer head (ft)

The general equation governing confined, transient, anisotropic, heterogeneous flow in two dimensions is:

$$\frac{\partial}{\partial \mathrm{x}}\left(K_{xx}\frac{\partial h}{\partial x}\right)+\frac{\partial}{\partial \mathrm{y}}\left(K_{yy}\frac{\partial h}{\partial y}\right)-W=S_s\frac{\partial h}{\partial t} \quad \text{(Eq. 2)}$$

where:

K_{xx} is hydraulic conductivity in the x-dimension (ft/day)

K_{yy} is hydraulic conductivity in the y-dimension (ft/day)

h is aquifer head (ft)

W is the rate of aquifer recharge (1/day)

S_s is specific storage (1/ft)

t is time (days)

The ESPAM comprises both a steady state and transient, two-dimensional, isotropic representation of the eastern Snake River Plain aquifer. The isotropic

representation means that $K_{xx} = K_{yy}$. In a numerical model, individual model cells are homogeneous. Heterogeneity is represented by the spatial variation of properties such as transmissivity, on a cell by cell basis. Therefore, the governing equations for a numerical model are the same as for a homogeneous system. Multiplying Equations 1 and 2 by b/T, where b is saturated thickness (ft) and T is aquifer transmissivity (ft^2/day), yields the following:

$$\frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2} - W\frac{b}{T} = 0 \quad \text{(Eq. 3)}$$

and

$$\frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2} - W\frac{b}{T} = \frac{S}{T}\frac{\partial h}{\partial t} \quad \text{(Eq. 4)}$$

where:

T is aquifer transmissivity (ft^2/day)

h is aquifer head (ft)

W is the rate of aquifer recharge (1/day)

S is storativity (dimensionless)

t is time (days)

b is aquifer thickness (ft)

Equations 3 and 4 represent the governing equations used for representing groundwater flow in the ESPAM steady state and transient models, respectively.

Flow between the aquifer and river or drain cells is governed by equations which are based on Darcy's law. Darcy's law is:

$$Q = -KA\frac{dh}{dl} \quad \text{(Eq. 5)}$$

where:

Q = discharge (ft^3/day)

A = cross-sectional area (ft^2)

K = hydraulic conductivity (ft/day)

dh/dl = hydraulic gradient (dimensionless)

In a numerical model, for both river and drain cells, the hydraulic conductivity term represents the conductivity of the river-bed or drain sediments which controls the flow between the river/drain and the aquifer. The gradient (dh/dl) represents the head differential between river stage (or drain elevation) and aquifer level.

In a finite-difference model, the ground-water flow equation is solved for each individual model cell and river or drain cell, preserving the mass balance of water. Each model cell can have individual properties representing aquifer transmissivity and storage. Similarly, all river and drain cells can have individual properties representing river/drain elevation and conductance. At every time step of the model, the equations are solved simultaneously using a numerical solver.

The ESPAM was constructed using MODFLOW2000, a finite-difference code widely used for ground-water modeling which was created by the U.S. Geological Survey (McDonald and Harbaugh, 1988, Harbaugh and others, 2000). The ESPAM was constructed using the Link-Module Gradient (LMG) solver (Mehl and Hill, 2000), however, the model can also be run using the Pre-Conjugate Gradient solver (Hill, 1990). With the LMG solver, the water budget closure criterion is .00001 and the dampening parameter is 1.0. The parameter estimation code, PEST version 8.3 (Doherty, 2004) was used to assist with model calibration.

MODFLOW2000 was selected because it is considered an industry standard for finite difference ground-water models. PEST was selected because of adaptability to the complexity of the model calibration where model results were compared with thousands of aquifer measurements during the calibration process.

Discretization

Finite difference modeling consists of breaking a large physical area into small volumes, which are called model cells, and simultaneously solving the numerical problem (Equations 3, 4 and 5) for each model cell. Additionally, if the model is transient, the total simulation time is also broken down into smaller time periods and the problem is solved at the end of each time period. In the case of ground-water modeling, the problem is being solved to determine aquifer head at each of the model cells and flux to drains and to/from rivers. This process of breaking the larger pieces down into smaller pieces is referred to as discretization.

For a uniform grid, the estimated aquifer head for each model cell represents the head at the center of the cell. If the cells are very large and the gradient is steep, interpolating head at locations other than at the center of the cell can introduce significant error.

Spatial Discretization

The spatial discretization of the model study area is the representation of the eastern Snake River Plain aquifer system in small volumes. The study area was overlain by a uniform 1 mile x 1 mile grid. The grid was intersected with the model boundary. Any cell within the model boundary is considered an active cell, or a cell for which aquifer head would be computed using the model. Any cell outside of the model

boundary is considered an inactive model cell and not part of the calculation of aquifer head.

Model Grid

The ESPAM grid consists of 104 rows and 209 columns. The grid rows are numbered with row 1 at the top of the grid. The grid columns are numbered from west to east, with column 1 being the west-most column. The grid origin is at the outside corner of model cell (1,1), the most northwest point of the model grid, and is at Idaho Transverse Mercator (IDTM) coordinates x=378,416.2 m and y=233,007.2 m (in feet: x=1,241,523 and y=764,459.2, latitude = 43.118806°, longitude=-115.49619 °). The reader should note that these IDTM coordinates are in the original IDTM system (IDTM 27) and not the IDTM83 system which was adopted in 2004. For more information on IDTM coordinates, the reader is encouraged to contact IDWR.

The model grid is rotated 31.4° counter-clockwise relative to an east-weat orientation. The rotation is selected to minimize the number of inactive model cells. Figure 13 shows the model grid, the origin and the orientation. The grid is comprised of model cells which are 1 mile x 1 mile square cells (5,280 ft x 5,280 ft). There are 11,451 active model cells. Selection of the 1 mile x 1 mile grid size was consistent with the density of data available for the study area and the steepness of gradients in the Snake River Plain aquifer. Figure 14 shows a close-up of the model grid in the Thousand Springs area (between the Kimberly and King Hill gages) and the density of observation wells in that area. This gives the reader a sense of the density of available data relative to the model grid size. Details of the model grid design are available in ESPAM Design Document DDM-015.

Model Layers

The ESPAM of the eastern Snake River Plain aquifer is a single-layer model. Previous models of the aquifer have contained both single (Cosgrove and others, 1999) and multiple (Garabedian, 1992) layers. It is generally agreed that the regional eastern Snake River Plain aquifer resides in a single large stratigraphic unit, consistent with a single layer model (Whitehead, 1986).

There are localized lenses of sediments in some locations on the plain (the Rigby Fan and the Burley-Rupert area), which may contain locally elevated water levels. When the ESPAM was being designed, it was agreed among the ESHMC that the option of adding a top layer to represent the sedimentary units would be explored only if time permitted and data were available. Investigation showed that there are little data available to support calibration of separate layers representing these locally elevated zones and ESHM Committee members agreed that a single layer model was sufficient. More information on the choice of using a single layer representation is available in ESPAM Design Document DDM-003.

Temporal Discretization

The ESPAM includes both a steady state and a transient model. Steady state simulation does not involve a time factor (Eq. 3). For a transient model, it is necessary to select a) the total time span for the model calibration period, b) the model stress period interval and c) the number of time steps in each stress period for which aquifer head and river gains will be calculated. Decisions on model calibration time span and temporal discretization were made by the ESHM Committee.

The criteria used to select the model calibration period included a) the period should represent a wide range of recharge and discharge, b) reliable data should be

available for the period, c) the period should be long enough to allow the ground-water model to adequately predict long-term aquifer trends and d) the period should reflect current land use and irrigation practices. The ESHM Committee selected a model calibration period of 22 years, from May, 1980 through April, 2002. The starting date was selected to coincide with the extensive data collection effort on the eastern Snake River Plain which was done by the USGS as part of the RASA project. The end date was originally set one year earlier (April, 2001); however, since the 2001-2002 water year was an extreme drought year, the choice was made to extend the model end period by one year to include the 2001-2002 water year. This decision had the added benefit of allowing the modelers to use field measurements from the 2001-2002 water year. The period of May, 1980 through April, 2002 includes the wettest year on record (1997), early drought years (1987-1990) and the starting years of the current drought period (2000-2002). A calibration period with a wide variation of recharge and discharge results in calibration targets (river gains, spring discharges and aquifer water levels) which provide a better constraint on the calibrated model parameters (aquifer transmissivity and aquifer storage and riverbed conductance).

In a MODFLOW model, a stress period is the length of time during which aquifer recharge and discharge (aquifer stresses) are held constant. In the ESPAM, because the hydrology is dominated by irrigated agriculture, 6-month stress periods (182 days during the irrigation season and 183 days during the non-irrigation season) were selected. The irrigation season stress period starts on May 1 and ends on October 31 and the non-irrigation season starts on November 1 and ends on April 30. The ESHM Committee agreed that, if calibration were successful with the 44 6-month stress periods, an attempt

would be made to calibrate with 6-month stress periods representing the first 21 years and twelve 1-month stress periods representing the last year. This was attempted during model calibration; however, there was insufficient resolution in many components of the recharge and discharge data to support the 1-month stress periods. Hence, the final calibrated ESPAM transient model has 44 6-month stress periods. Table 2 lists the dates represented by each of the 44 transient stress periods.

In ground-water modeling using MODFLOW the stress period is subdivided into time steps. The ground-water flow equations are solved at every time step. Even though the same aquifer stress is being applied during the whole stress period, aquifer water levels and river gains are changing throughout the stress period (the aquifer water levels and river gains are responding to the applied stress). By further discretizing time using time steps, the model predicts these intermediate aquifer water levels and river gains, allowing comparison of predicted water levels and river gains with measured values and reducing uncertainty in model predictions. For ESPAM calibration, 10 time steps of equal length (18.2 days during the irrigation season and 18.3 days during the non-irrigation season) are used for each model stress period. Since each time step is 18.2 or 18.3 days in length, the net result is that aquifer water levels and river gains are estimated by the model every 18.2 or 18.3 days during the 22-year calibration period.

Model Boundary Conditions

In a numerical ground-water model, the boundary conditions can exert a great amount of control on the model solutions, particularly for steady state solutions. The selection of boundary conditions is a critical element of the conceptual design of any ground-water model.

The ESPAM employs several types of numerical model boundary conditions. No-flow boundaries are used around most of the perimeter of the model, simulating the physical contact between the aquifer and impermeable geologic formations. Specified flux boundaries are used to represent tributary underflow, non-Snake River reaches, wells where water is not locally applied for irrigation, recharge from precipitation on non-irrigated lands, irrigation conveyance loss and net recharge/discharge from surface- and ground-water irrigation. Head-dependent boundaries, where the rate of discharge to or from the aquifer is driven by a head differential between the aquifer and a hydraulically connected water body (such as a river reach or spring), are employed to represent some reaches of the Snake River and springs immediately tributary to the Snake River.

Geographic Boundary Conditions

The ESPAM boundary is based on the SRPAM and RASA aquifer boundaries, with some modifications. Figure 15 shows the ESPAM boundary, the RASA boundary, the SRPAM model boundary and irrigated areas. Because the ESPAM is intended for the conjunctive management of ground- and surface-water resources, the SRPAM and RASA boundaries were evaluated based on inclusion of irrigated areas. Modifications were made to expand the original aquifer boundaries to include irrigated acreage in the Kilgore, Rexburg Bench, American Falls and Oakley Fan areas (Figure 15). The Twin Falls tract, which is within the RASA boundary but not the SRPAM boundary, was excluded since the Snake River is deeply incised between Kimberly and King Hill, so there is no communication between the aquifers on the north and south sides of the Snake River.

In the King Hill area, the RASA boundary extends several miles further to the west than the SRPAM boundary. The decision was made to include that area in the ESPAM boundary, allowing inclusion of the King Hill gage on the Snake River. The model boundary was extended up the Big Lost River drainage to Mackay Dam in order to simplify the estimate of tributary underflow in that drainage. A result of the expansion of the model grid (beyond SRPAM) was the inclusion of approximately 294,000 acres of irrigated lands, which had a significant impact on the model water budget (addressed in a later section). The ESHM Committee felt, however, that this was necessary to support the need for model use for conjunctive management of surface- and ground-water resources.

In addition to the areal extent of the study area, an analysis was done of the bottom of the aquifer. In hydrogeology, the aquifer transmissivity (T) is equal to the saturated thickness (b) multiplied by the aquifer hydraulic conductivity (K). Since the bottom of the aquifer is unknowable in many locations, the imperfect understanding of the saturated thickness is compensated for by adjustments to K during model calibration. Stating this another way, it is the combined parameter, transmissivity (T=K*b) which is critical to understanding the movement of water in the aquifer. Neither the hydraulic conductivity nor the saturated thickness must be individually well understood. Although not overtly necessary to calibration of a model, knowledge of the bottom of the aquifer is of interest when interpreting modeling results. An estimate of the bottom of the aquifer allows the modelers to determine an estimate of hydraulic conductivity based on T and b. Additionally, when analyzing the potential non-linearities in an aquifer system, an

understanding of the magnitude of saturated thickness relative to aquifer drawdown is critical.

Whitehead (1986) published basalt thickness maps for the eastern Snake River Plain. The maps were based on borehole logs and geophysics at a limited number of locations. The ESHM Committee agreed that a delineation of the bottom of the eastern Snake River Plain aquifer which was based on Whitehead's work with an assumption of a minimum aquifer thickness at the aquifer margins of 200 ft was a reasonable approach. Figure 16 shows the kriged surface of the bottom of the aquifer assumed for the current study. Because there are very few data points available for delineation of the bottom of the aquifer, Whitehead used some presumed data points to delineate the bottom of the aquifer. For this model, some of Whitehead's presumed data points were used, some were modified and several points were established in the Thousand Springs region to establish the minimum aquifer thickness of 200ft. The locations of these data points are all shown in Figure 16. Figure 17 shows the locations at the aquifer margin where the aquifer thickness was set to 200 ft. More details about the determination of the bottom of the aquifer can be obtained in ESPAM Design Document DDM-012.

Hydrologic Boundary Conditions

Hydrologic boundary conditions are used to represent the interaction of the aquifer with rivers, streams, lakes and springs. Strictly speaking, the representation of aquifer recharge and discharge is also a hydrologic boundary condition. The following sections discuss how rivers, streams and springs are represented in the ESPAM. As previously mentioned, some reaches of the Snake River and some springs discharging to the Snake River are represented as head-dependent flux boundaries. Tributary

underflow, non-Snake River streams and rivers, and irrigation conveyance loss are represented as specified flux boundaries. All other components of aquifer recharge and discharge (e.g. wells and net recharge/discharge from surface- and ground-water irrigation) are represented as a specified flux in each model cell. Estimation of aquifer recharge and discharge is discussed in the section on Model Water Budget.

MODFLOW Representation of Head-Dependent Boundaries

Head-dependent boundaries are boundaries where the rate of flux between the surface water body and the aquifer is dependent upon the head gradient between the surface water body and the aquifer. Head-dependent boundaries are used to represent surface water bodies which are hydraulically connected to the aquifer. These surface water bodies can be either gaining water from or losing water to the aquifer. In the case of springs, the model representation is strictly a discharge out of the aquifer through the spring.

The flow between the aquifer and a hydraulically connected surface water body is governed by Equation 5. In the MODFLOW River Package, Equation 5 is implemented in terms of a) stage of the surface water body, b) aquifer water level and c) a conductance term describing the hydraulic conductivity of the riverbed (or spring) sediments and the wetted areas of the riverbed. The user specifies river stage, elevation of the bottom of the river sediments and conductance of the riverbed sediments. As long as the water level in the aquifer is above the elevation of the bottom of the river sediments, the discharge to (or from) the river is calculated as:

$$Q_{riv} = C_{riv}(h_{riv} - h_{aq}) \quad \text{(Eq. 6)}$$

where:

Q_{riv} is the discharge to or from the river (ft^3/day)

C_{riv} is the riverbed conductance (ft^2/day)

h_{riv} is the head in the river (ft)

h_{aq} is the head in the aquifer (ft)

Figure 18 shows conceptually how river leakage is calculated in MODFLOW. As long as the aquifer head is above river bottom, the discharge to or from the river is calculated based on the head differential. When the aquifer water level drops below the bottom of the riverbed sediments, the river becomes perched and leaks at a constant rate.

Springs in the ESPAM are represented using the MODFLOW Drain Package. The Drain Package is identical to the River Package with one important distinction: the drain package only allows water to exit the aquifer. When the aquifer water level drops below the drain (spring) elevation, the drain or spring shuts off until the aquifer water level recovers. The equation governing aquifer discharge to drains in MODFLOW is:

$$Q_{drn} = C_{drn}(h_{aq} - el_{drn}) \quad \text{(Eq. 7)}$$

where:

Q_{drn} is the discharge to the drain (ft^3/day)

C_{drn} is the drain conductance (ft^2/day)

h_{aq} is the head in the aquifer (ft)

el_{drn} is the drain elevation (ft)

ESPAM Head-Dependent River Boundaries

Head-dependent river boundaries are used in the ESPAM to represent most of the Snake River above Milner Dam. Two hundred and thirty river cells were established to represent the Snake River above Milner Dam. Since riverbed conductance is a lumped

parameter (ie. it represents multiple physical attributes) and impossible to measure, it is commonly estimated during model calibration. Figure 19 shows the ESPAM head-dependent river cells and the aggregation into reaches. Water balance calculations (accomplished using the IDWR Reach Gain and Loss program) indicate that there is virtually no leakage in the reach between Minidoka and Milner, so the reach is not represented in the model. Table 3 lists the model cells used in the MODFLOW River Package and the assigned reach.

The MODFLOW River package requires river stage, elevation of the river bottom and riverbed conductance for each river cell. Determination of river stage and river bottom elevation will be discussed in this section. The estimation of riverbed conductance will be discussed in the section on model calibration. River stage (or elevation of the river surface) was determined by projecting a GIS coverage of the Snake River onto the 10 meter digital elevation models (DEMs) available from the USGS. Once this projection was accomplished, the river elevation was digitized from the DEMs. The 95% confidence interval on deriving elevations using 10 m DEMs is estimated at 1.21 ft +/- 1.17 ft (ESPAM Design Document DDM-010).

Elevation of the river bottom is important, particularly in reaches which may transition between hydraulically connected and perched. Estimation of the river bottom elevation carries a high degree of uncertainty, as it is difficult to measure and may vary greatly at different locations. Elevation of the river bottom is typically only known at gaging stations. The ESHM Committee decided that the best approach for estimating the elevation of the river bottom was to interpolate river bottom depth between the known points at gaging stations. Using this method, the differential between river stage and the

bottom of the riverbed ranged between 33 feet and 63 feet. For more information on estimation of river stage or the elevation of the bottom of the riverbed, the reader is referred to ESPAM Design Document DDM-010.

Head-Dependent Spring Representation

In the ESPAM, springs discharging to the Snake River in the Thousand Springs region (between the gaging stations at Kimberly and King Hill) are represented using the MODFLOW Drain Package. As previously discussed, the Drain Package is very similar to the River Package in that discharge from the aquifer through the drain is calculated based on the head differential between the aquifer water level and the drain elevation. If the aquifer water levels drop below the drain elevation, discharge from the drain ceases until the aquifer water levels recover. In the Thousand Springs region, the Snake River flows through a deeply incised canyon, allowing little opportunity for water to discharge from the river to the aquifer. Therefore, selection of the Drain Package is consistent with the physical system.

Forty-five drain cells were used to represent spring discharge in the Thousand Springs area. Unlike the river cells which represent the upper reaches of the Snake River, the drain cells are not contiguous along the Thousand Springs area. The drain cells were sited by mapping springs with significant discharge from the Covington and Weaver (1990) maps published by the USGS. The Covington and Weaver maps were also used to establish initial drain elevations; however, drain elevations were modified during calibration (see the section on model calibration). Table 4 lists the model cells represented with the MODFLOW Drain Package.

Discharge of individual springs or individual drain cells is difficult to represent with a regional scale model. Consequently, the ESHMC agreed that drain cells should be aggregated into reaches that were more consistent with the scale of the model. Aggregation of the drain cells into reaches was accomplished based on an analysis of a) discharge of individual groups of springs and b) cumulative discharge of springs along the entire Thousand Springs reach. Figure 20 shows the cumulative spring discharge along the Thousand Springs reach starting at Devils Washbowl (near Milner dam). Inspection of Figure 20 shows that there are some natural changes in the slope of cumulative discharge which supported aggregation of groups of springs into reaches. In Figure 20, it can be seen that cumulative discharge progresses at a fairly constant slope between Devils Washbowl and Buhl. At approximately the Buhl gage, the slope of the cumulative discharge curve increases until the springs at the Thousand Springs power plant. The springs at the power plant have extremely high discharge, causing a dramatic rise in cumulative discharge. The slope of the cumulative discharge is lower between Thousand Springs and Malad, where the cumulative discharge curve has a second dramatic rise. Between Malad and Bancroft, the cumulative discharge curve again has a lower slope. Analysis of Figure 20 resulted in the springs being aggregated into the following six reaches, shown in Figure 21: Devils Washbowl to Buhl, Buhl to Thousand Springs, Thousand Springs, Thousand Springs to Malad, Malad, and Malad to Bancroft. The color-coded squares in Figure 21 represent individual model cells where MODFLOW drains are used to represent spring reaches.

Initial values of drain conductance for the drain cells along a spring reach were estimated based on the discharge for the group of springs and the estimated head

differential between the aquifer and the spring elevation. Drain conductances were calibrated during model parameterization. This will be discussed further in the model calibration section. More details on the location of drain cells, aggregation of the spring reaches and estimation of initial drain conductance can be found in ESPAM Design Document DDM-018.

Specified Flux Boundaries

Specified flux boundaries are used to represent flow to or from the aquifer which occurs at an estimated rate and is not driven by a head differential. Specified flux boundaries are typically used to represent the interface between the aquifer and a water supply which is not hydraulically connected. In the ESPAM, tributary basin underflow, percolation from irrigation and precipitation on non-irrigated lands, seepage from perched rivers and irrigation conveyance losses are represented using specified flux boundaries. This section describes the specified flux boundaries. The rate of specified flux used in the ESPAM, including pumping, will be discussed in the Water Budget section.

Underflow from Tributary Basins

Tributary underflow represents the subsurface discharge of water from a tributary basin into the eastern Snake River Plain aquifer. Because tributary underflow is subsurface flow, it is difficult to estimate. Underflow from 22 tributaries is represented in the ESPAM. Table 5 lists the tributary basins, for which underflow is represented in the ESPAM. Figure 22 shows the location of each of the tributary basins on the Snake Plain. In Figure 22, the individual model cells which are used to enter the specified flux are highlighted. Appendix A contains a table listing the model cells associated with each

tributary (Table A-1). The estimated flux for each tributary is evenly distributed across the model cells assigned to that tributary in each stress period. Estimation of the rate of tributary underflow discharge is discussed in the water budget section.

Perched River Seepage

The ESPAM has 12 locations at which perched river seepage is represented. These reaches represent surface water bodies other than the Snake River. Perched reaches of the Snake River (other than the previously mentioned reach between Minidoka and Milner) are represented using the MODFLOW River Package. Table 6 lists the non-Snake River perched reaches. Strictly speaking, not all of the perched reaches are river reaches. Several flood control sites are represented in the same manner as perched river reaches. Figure 23 shows the location of each perched reach. The model cells in which perched seepage is represented are highlighted in Figure 23. Appendix A contains a table listing the model cells associated with each perched reach (Table A-2). The estimated flux for each perched reach is evenly distributed across the model cells assigned to that perched reach in each stress period. Estimation of the rate of perched seepage is discussed in the water budget section.

Irrigation Conveyance Loss

As irrigation water is delivered to fields, there is leakage from the canals and laterals. This is referred to as irrigation conveyance loss or canal leakage. The eastern Snake River Plain has approximately 1,000,000 acres of land irrigated by surface water which is delivered by canals and laterals. It would be impossible to characterize leakage from all of the canals and laterals, so leakage is only explicitly represented from the largest of the canals and canals where the seepage was determined to affect simulation of

spring discharges. Other canal leakage is assumed to have approximately the same spatial distribution as incidental recharge from irrigation and is implicitly included in the irrigation recharge calculation. Canal leakage rates are estimated as a percentage of surface water diversions and are discussed in the water budget section.

Leakage from the larger canals is represented in the ESPAM as specified flux boundaries. The ESPAM has 5 locations at which irrigation conveyance loss is represented. Table 7 lists the represented canals. Figure 24 shows the location of each leaky canal and the model cells in which canal seepage is represented. Appendix A contains a table listing the model cells associated with each canal (Table A-3). The estimated flux for each canal is evenly distributed across the model cells assigned to that canal in each stress period.

Model Initial Conditions

Estimates of aquifer head for each model cell at the beginning of a simulation form the initial model conditions. Of primary concern are initial aquifer water levels or starting heads for the transient simulation. For the steady state ESPAM, the starting heads are set at an arbitrary initial value of 7000 ft. Because a steady state simulation is run until there are no further changes in aquifer water levels, the starting heads are not important. The simulation will continue running and balancing the water flow between each model cell until the system reaches equilibrium and there are no further changes in water levels.

For the transient ESPAM, the starting water levels are the ending heads from the steady state model. In the physical system, water levels fluctuate with location and with season, largely in response to irrigation practices. It is very difficult to accurately

estimate the water levels throughout the aquifer at an instantaneous point in time, so the ESHM Committee agreed that using the ending heads from the steady state simulation was a reasonable point for starting heads for the transient simulation. The ending steady state heads will represent an average water level condition—high in some locations and low in others. As the transient model progresses in time, the water levels will be driven by the recharge and discharge and the physical aquifer properties (transmissivity, aquifer storage and riverbed conductance). This means that changes in aquifer water levels during the first few years of transient simulation are less meaningful than the later years, after the initial head conditions have been overcome.

Model Water Budget

The model water budget is one of the most important elements of a ground-water model. The water budget comprises the accounting of all recharge and discharge to the aquifer both for the steady state period and for each model stress period. By definition, steady state means that there are no changes in aquifer water levels (which equates to no change in aquifer storage). Therefore, for steady state, the inflows must balance with the outflows (Eq. 3). For each transient stress period, the inflows minus the outflows must balance with the change in aquifer storage (Eq. 4).

Water use, and therefore the hydrology, on the eastern Snake River Plain is dominated by irrigated agriculture. The major sources of recharge to the aquifer are incidental recharge from surface water irrigation, tributary underflow, leakage from canals and rivers and recharge from precipitation on non-irrigated lands. The major sources of discharge from the aquifer are evapotranspiration and spring discharges to the Snake River (Figure 8). There is a lot of natural variation in water supply from year to

year. Several large reservoirs on the Snake River help to buffer the water supply available for irrigation, but supply is still limited in some years.

Estimation of the water budget for the ESPAM required estimation of all of the above-mentioned components. Estimation of some of these components entailed multiple steps. In addition to the major components of the water budget, there are several smaller components which were also estimated and are discussed below.

Land Use

One of the first steps in evaluating water use for a study area is an evaluation of land use. Recharge to the aquifer can vary greatly among different land uses. For example, on land irrigated with surface water, the amount of irrigation water applied generally exceeds the consumptive use, so there is a net recharge to the aquifer. On the other hand, on lands irrigated with groundwater and on wetlands, there is a net extraction from the aquifer to meet consumptive use. Identifying land use is an important part of estimating the water budget, particularly in an area where the water use is dominated by irrigated agriculture, such as in the eastern Snake River Plain.

To evaluate irrigated areas for the ESPAM, multiple sources of data were evaluated. One of the problems with using land use analyses from different sources is that it is difficult to discern whether changes in land use reflect actual changes over time or different analysis techniques. The modeling team did an exhaustive job of comparing data from multiple sources and ground-truthing the land use analyses, as documented in ESPAM Design Document DDW-015. Initially, the ESHM Committee decided to employ land use analyses based on imagery from 1980, 1992 and 2000. The 1980 (RASA80LC, IDWR, 1980) analysis is a land classification of LANDSAT data

performed by the Idaho Image Analysis Facility of IDWR (IDWR, 1982), using the "thematic mapper" LANDSAT sensor and Vicker's classification algorithms, which are not directly comparable with later LANDSAT data and methods (Morse, 2001). The 1992 (SNAKLC92, IDWR, 1997b) analysis is based on 1987 aerial photography and extensive field work. The 2000 (ESPAC2000, IDWR, 2002a) classification was performed by IDWR specifically for this project, using classification of multiple LANDSAT images, with a two-week to one-month image frequency. These three land use analyses were initially selected to represent the changes in irrigated area between 1980 and 2002.

During model calibration, comparison of the water budget with the aquifer water levels and spring discharges indicated that the slight trend of decreasing irrigated acreage over time, as evidenced by the land use analyses of these three sets of imagery, was inconsistent with trends in measured modeling targets. Inspection suggested that the differences in spatial distribution between the three land-cover data sets were minor and the differences were distant from river or spring reaches of concern. The decision was made by the ESHM Committee that the final model calibration would use the irrigated lands analysis which was based on the SNAKLC92 data set for the entire calibration period. The extensive ground-truthing which was done for the SNAKLC92 data set provided the highest confidence in the land use analysis.

The location of wetlands was derived from a 1991 analysis of LANDSAT imagery done by IDWR (SRBAS91LU, IDWR, 1994). Some of the available land use analyses did not identify wetlands. For the land use analyses which did identify

wetlands, known wetland locations were ground-truthed. The SRBAS91LU coverage had the most reliable identification of wetlands.

Identification of cities was compared among the available land use analyses. 2000 LANDSAT images of the City of Idaho Falls were compared with the analyses which did identify cities. The ESHM Committee agreed that the SRBAS91LU (IDWR, 1994) analysis provided the most accurate delineation of cities. For further details on the delineation of wetlands and cities, the reader is referred to ESPAM Design Document DDW-015.

Figure 25 shows a composite coverage of irrigated lands, wetlands, cities and soil types on non-irrigated lands (to be discussed in a later section). Figure 25 reflects the land use which was used in compiling the ESPAM recharge and discharge.

Estimation of Recharge/Discharge

Estimation of aquifer recharge and discharge includes estimation of many intermediate variables which are used to calculate the net recharge to the aquifer. For example, even though precipitation contributes to aquifer recharge, it is actually used as an intermediate variable for estimating recharge on surface-water irrigated lands, discharge from ground-water irrigated lands and recharge on non-irrigated lands. The reason it is treated as an intermediate variable is that some estimate must be made of the amount of precipitation which evaporates versus the amount which is available to recharge the aquifer. Similarly, evapotranspiration on irrigated lands, canal seepage, irrigation return flows (irrigation water returning to the surface water system which includes end of canal spills and surface run-off), off-site pumping and crop mix are used as intermediate variables in the estimation of aquifer recharge and discharge associated

with irrigation. The next sections will discuss how these variables are used in the estimation of net aquifer recharge as well as how these variables are estimated.

Other components of aquifer recharge and discharge are estimated directly. These include tributary basin underflow, perched river seepage, pumping for surface water replacement and recharge on non-irrigated lands.

The following sections describe a) the estimation of all of the components of the water budget including both intermediate variables and directly estimated components and b) how the various components are used in the water budget estimation.

Recharge on Irrigated Lands

Irrigated agriculture can result in a net recharge to the aquifer (surface-water irrigation) or a net discharge from the aquifer (ground-water irrigation). The land use analysis described above identified irrigated agriculture, but a separate analysis was required to delineate surface-water irrigated lands from ground-water irrigated lands.

Estimation of net recharge to the aquifer from surface-water irrigated lands requires surface water diversion, irrigation return flow, canal leakage, precipitation and evapotranspiration data. The calculation is as follows:

$$\text{Field Delivery} = \text{Diversions} - \text{Canal Leakage} - \text{Return Flows} \quad \text{(Eq. 8)}$$

$$\text{Net Recharge (surface)} = (\text{Field Delivery} + \text{Precipitation}) - (\text{ET} \times \text{Adjustment Factor}) \quad \text{(Eq. 9)}$$

Ground-water pumping rates have only been measured since the mid-1990s on the ESRP. The measurement methods are not consistent throughout the plain, so measurement data is not yet reliable. Additionally, the data that do exist record gross pumpage and not net extraction. The lack of historical ground-water pumping

measurement data and the lack of consistency in the measured data required an alternative method of estimating net discharge from ground-water irrigation. Net discharge from the aquifer from ground-water irrigated lands is estimated using evapotranspiration, offset by available precipitation. The rationale behind this method of estimation is that any ground water which is pumped in excess of crop demand (ET) will infiltrate back into the aquifer. The calculation is as follows:

Discharge from aquifer = Precipitation - (ET x Adjustment Factor) (Eq. 10)

By agreement, the ESHM Committee and modeling team decided that surface runoff was negligibly small and could be disregarded for this calculation. Similarly, because precipitation and ET were estimated for the full year, it was agreed that soil moisture content could also be neglected.

When the precipitation exceeds the demand, there will be a net recharge to the aquifer on ground-water irrigated lands. When demand exceeds precipitation, there will be a net discharge.

Precipitation

Precipitation for the study period was estimated using PRISM (Parameter-elevation Regressions on Independent Slopes Model) maps produced by the Oregon Climate Service and the Spatial Climate Analysis Service (Daly and Taylor, 1998). PRISM uses point data, a digital elevation model, and other spatial data sets to generate gridded estimates of several spatial and temporal climatic parameters, including precipitation. A summary of the steps taken to estimate precipitation is provided below. For more detailed information on the estimation of precipitation for the ESPAM, the reader is referred to ESPAM Design Document DDW-011.

PRISM distributes point measurements of monthly, seasonal, and annual precipitation to a geographic grid of four kilometers by four kilometers. By use of a resampling algorithm, two-kilometer by two-kilometer resolution grids can be estimated. These grids are produced in a GIS-compatible latitude-longitude grid or a gridded map projection.

Monthly PRISM maps for the study area for 1980 through 1997 were obtained from the Spatial Climate Analysis Service. As of the estimation of the ESPAM water budget, maps were not available for 1998 through 2002. For consistency in precipitation data estimation, a method was devised, with the concurrence of the ESHM Committee, to interpolate precipitation data between weather stations for the years 1998-2002. The method is described below.

Precipitation data for the years 1998 to 2002 were purchased from NOAA (http://lwf.ncdc.noaa.gov/oa/ncdc.html) for all NOAA stations on the eastern Snake River Plain. These data series include precipitation values, in inches, and the departure from normal values, in inches.

In order to maintain precipitation data consistency over the entire 22-year study period, 1998 to 2002 NOAA data were processed with 30-year average PRISM data to achieve consistent data formatting with the PRISM two-kilometer by two-kilometer grids for each monthly precipitation map. This 1998 to 2002 NOAA processed dataset was then used to supplement the 1980 to 1997 PRISM dataset. A detailed description of the NOAA data processing follows.

Using the NOAA departures from normal values and the NOAA monthly actual precipitation values, a normal for each NOAA station was calculated. Then, actual

precipitation as a fraction of the normal was calculated for each NOAA station. This resulted in a multiplier which, when multiplied by the normal value, gave the actual NOAA precipitation value. A set of multipliers was calculated for each month for the period of January 1998 to April 2002. Using ArcView3.2, the point-value multipliers were interpolated to a raster surface of NOAA multipliers. The NOAA multipliers were applied to the PRISM 30-year average monthly precipitation data using ArcView 3.2. The multiplier datasets were applied to the 30-year average PRISM rasters to produce monthly precipitation rasters for the 1998-2002 period.

Once monthly precipitation maps were generated for the full model period, the monthly rasters were summed into the same time periods as the ESPAM stress periods. Figure 26 shows example PRISM precipitation maps for average precipitation for the 22-year model period, for both the irrigation season and the non-irrigation season. Inspection of Figure 26 shows the great difference between irrigation season and non-irrigation season precipitation on the ESRP. Figure 27 shows the annual total precipitation for each year of the study period. Inspection of Figure 27 shows that there is a great degree of annual variation in precipitation.

Crop Mix

Knowledge of the mix of grown crops is necessary for the estimation of evapotranspiration. Differences in crop mix can change average ET by as much as ten percent, which translates into 1.7×10^{10} ft^3 (400,000 AF), or approximately seven percent of the aquifer water budget, assuming two feet of ET on 2,000,000 irrigated acres and a 6,000,000 acre-foot aquifer budget. The final crop mix used for the ESPAM was calculated based on data from several sources of crop statistics data, as discussed below.

The primary data source is the National Agricultural Statistics Service (NASS) crop report data, which are based on county-wide surveys of farm operators. These data are available in three formats for the study area. These are the Published Estimates Data Base On Line (USDA, 2000), the US Agricultural Census (USDA, 1992, 1997) and the Idaho Agricultural Statistics (Idaho Department of Agriculture, 1981 - 2002) reports. The Published Estimates Data Base On Line (PEDB) version provides county-wide acres planted and harvested, by crop. These reports do not include alfalfa hay for the earlier years of the study, so 1982 and 1987 values from the US Agricultural Census (Ag Census) version of the NASS data for alfalfa were used. The Idaho Agricultural Statistics (IAS) report was used to fill in gaps in the PEDB potato data. The Agricultural Census reports provide more detailed results, including details of irrigated and non-irrigated acreage by county, for the years 1982, 1987, 1992, and 1997. The IAS report is compiled from NASS data and includes yearly values for irrigated and non-irrigated acreage, by county, for major crops. As of the time of this study, the IAS data were available for years 1980 through 2001. Many of the county agents interviewed recommended the NASS/IAS data.

About half of the counties in the study area have farmed land both inside and outside the study area (Figure 28). It is possible that the crop mix outside the study area is different than the mix inside. The potential errors associated with these crop differences were first assessed by estimating a “reasonable” and “extreme” crop mix for lands inside the study area, and calculating volume of ET for each. The analysis was performed for Bonneville and Cassia Counties. The result of the analysis was that “irrigated only” crop report data provided a better representation of the study area than

did county-wide data. Therefore, whenever possible, “irrigated only” (agricultural census or IAS) data were used.

The final data compilation uses the published Idaho Agricultural Statistics (Idaho Department of Agriculture 1981 - 2002) data with some refinements, as detailed in ESPAM Design Document DDW-001. Final crop mix fractions by year and county are listed in Table A-4 in Appendix A. The crop evapotranspiration estimates compiled from crop mix data and reference evapotranspiration data indicated that year-to-year variation in total crop consumptive use is very small. A more detailed description of the evaluation of crop mix for the ESPAM can also be found in ESPAM Design Document DDW-001.

Evapotranspiration

One of the largest components of discharge on the ESRP is evapotranspiration, a combined variable encompassing evaporation and plant transpiration. Evapotranspiration is controlled by climate as well as crop and soil characteristics. Climate affects the evaporative power of the atmosphere, reflecting the energy available to drive evapotranspiration and the capacity of air to accept evapotranspired water. Soil and plant characteristics control the crop’s ability to extract water from the soil, and biological characteristics of the crop control the transpiration response to evaporative power. Soil texture, surface wetness and condition and shading by plants control the soil’s response to evaporative power. Although far more water evapotranspires during the growing season, there is still measurable evapotranspiration during the non-growing season. For the ESPAM, growing season ET was estimated separately from non-growing season ET.

Growing season evapotranspiration was estimated primarily using an alfalfa reference ET scaled by crop coefficients. The alfalfa reference ET is available for each

NOAA weather station within the ESRP. Allen (2002) evaluated five different ET calculation methods. The Kimberly-Penman Alfalfa Reference method was chosen as most suitable for the modeling application (Allen, 2003). This method was developed with Idaho empirical data and of the five methods is the most directly comparable to the reference ET reported in Estimating Consumptive Irrigation Requirements for Crops in Idaho (Allen and Brockway, 1983) data and to Agrimet (U.S. Bureau of Reclamation, 2003) estimates.

The selected data series provides only reference ET, but calculation of crop ET also requires crop coefficients (Kc values). Coefficients for individual crops were extracted from the original Allen and Brockway (1983) data by dividing individual crop ET by reference ET, for each weather station each month. The original data only include typically grown crops for each location. To avoid calculating zero ET if an atypical crop is grown, Kc values for all crops were assigned to all weather stations. Missing values were supplied from nearby stations. The variation of Kc between weather stations for any given crop is low (Allen, 2003). Because the data for each county include values for all typically grown crops, missing values represent rarely-grown crops. Therefore, this substitution will affect only a few acres within any stress period and has a very low potential of introducing error. An average Kc value was determined for each county which was an average, weighted according to the proportion of crops, from the nearest NOAA station data. This was performed for each model stress period.

ET estimation for this project included a remote sensing analysis of ET using the METRIC algorithm (Allen and others, 2002; Allen and others, 2005; Morse and others, 2000) for the 2001 growing season. METRIC results were used to calculate ET

adjustment factors. ET adjustment factors allow adjustment of ET to account for deviations from a perfectly managed crop such as a) water shortage, b) crop disease or c) post-harvest watering. ET adjustment factors may also reflect differences in ET due to source of irrigation water or method of application. Unique ET adjustment factors were evaluated for a) sprinkler or furrow application, b) ground water or surface water source and c) irrigation entity. The METRIC analysis indicated that the Kimberly-Penman estimates of ET are consistent with crops which are furrow-irrigated, but that crops irrigated with sprinklers have approximately 5% higher ET. For the ESPAM calibration, ET adjustment factors were set at 1.0 for all furrow application and at 1.05 for all sprinkler application. For more information regarding ET adjustment factors, the reader is referred to ESPAM Design Document DDW-021.

Though crops do not actively transpire in the winter time, evaporation and sublimation continue. For the ESPAM, winter-time ET is based on experiment data collected over several years at Kimberly, Idaho (Wright, 1993). The average winter ET from the Wright study is reported in Table 8.

Except for February, these values should generally be representative of the entire study area. The February value is representative of the lower-elevation portions of the study area, but February ET for higher elevation areas that are still snow covered in February is probably closer to the January average from Kimberly (personal communication, Wright, 2003). Snow increases the reflection of solar radiation back into the atmosphere, reducing the energy available to drive evaporation or sublimation. To adjust for differences in snow cover, February ET was scaled by elevation. February ET at Twin Falls (elev. 3770 feet) was set to 1.0 mm/day, and at Rexburg (4920 feet) to 0.6

mm/day. ET at other locations was adjusted using linear interpolation between the elevations at Rexburg and Twin Falls according to the equation:

ET (mm/day) = -0.0003478 x Elevation (feet) + 2.3112 (Eq. 11)

For stations higher in elevation than Rexburg, December and January ET were adjusted to be no higher than the elevation-adjusted February value. November ET was adjusted to be no higher than 120% of the adjusted February value. Table 9 lists the resulting winter-time ET values for all stations, converted to feet per month.

Figure 27 shows the annual total evapotranspiration for each year of the study period. Inspection of Figure 27 shows that there is some degree of annual variation in evapotranspiration, however, ET is relatively constant.

Source of Irrigation Water

Net recharge from surface-water irrigation is the largest component of the water budget. The second-largest component of the water budget is net withdrawal (calculated as consumptive use, or evapotranspiration) due to ground-water irrigation. The source of water for individual parcels must be identified so that diverted volumes of surface water are applied to the appropriate spatial locations. In the ESRP, aquifer water levels respond to surface-water irrigation by rising during the irrigation season and declining during the non-irrigation season. Aquifer response to ground-water irrigation is exactly opposite.

The source of irrigation water also affects the calculation of consumptive use, which depends in part on evapotranspiration (ET) adjustment factors, application method (sprinkler or gravity), and the reduction factor for non-irrigated inclusions within irrigated lands. For an individual parcel, the ET adjustment factor and sprinkler percentage from the local surface-water irrigation entity or the local ground-water

irrigation polygon are applied, depending on the water source identified for the parcel. The source of irrigation water by parcel is also required for model scenarios; for example, a hypothetical scenario might represent curtailment of a specific source of irrigation.

Water rights data provide the best information regarding source of irrigation water for each parcel of land. Many irrigated lands are either 100% surface-water irrigated or 100% ground-water irrigated. However, some irrigated lands have mixed ground water and surface water sources. This has typically occurred where surface water sources were inadequate, and supplemental ground water sources have been developed. The following sections describe the method used to determine the source of irrigation water and the method used to calculate recharge on mixed-source lands. A more detailed description of the assignment of irrigation source may be found in ESPAM Design Document DDW-017.

Geographic Information Systems (GIS) technology and Water Measurement District and Ground Water District records of actual well diversion volumes have recently become available. These sources were used for determining the source of irrigation water, in conjunction with Snake River Basin Adjudication data base records, which reflect varying degrees of resolution in the adjudication process. The adjudication data reflect accomplished changes not shown in water rights data. The adjudication data also represent legitimate “beneficial use” rights perfected before the statutory requirement to obtain a state permit for a water right. Adjudication claims are the users’ representations of water use, and exist for the entire plain. Recommendations are Idaho Department of Water Resources’ findings from investigation of claims. As of the time of this study, recommendations existed for about 2/3 of the study area. The court’s

determination of the adjudicated water right is called a partial decree. At the time of this study, partial decrees existed for a much smaller portion of the study area. Not all the partial decree data were available for automated electronic querying.

The map identifying water source by 40-acre quarter-quarter section is compiled from IDWR adjudication data with manual adjustments. Using GIS, the map identifying water source is combined with the map of irrigated lands (Figure 25) to identify irrigation water source for all irrigated lands. Figure 29 shows the GIS map of water source used in model calibration.

There are some limitations to the available water rights data. The ground-water diversion volume data only cover the years 1997 through 2002, and may have missing values, especially for the earlier years. These data were used to verify irrigation water source assignment which was based on adjudication data. The adjudication claims are uninvestigated representations of water users. Recommendations and partial decrees reflect the legal authorization to use water, not necessarily the actual practice. Because of the common occurrence of overlapping water rights, the ratio of ground-water to surface-water rights in a quarter-quarter section is not useful for determining the mix ratio on mixed-source lands.

Potential errors in the mix ratio apply only to the 13% of the quarter-quarter sections identified as mixed-source in the adjudication data. The modeling team, in conjunction with the ESHM Committee, developed a method for apportioning the mixed-source lands to either ground-water or surface-water irrigation. Consumptive use for mixed-source irrigated lands was evaluated for each irrigation entity. Assuming a requirement of 4 feet of delivered water (to meet consumptive use, conveyance loss and

irrigation inefficiencies), the team estimated how many acres could be satisfied by the recorded diversions. The balance of the irrigated acres was assigned to ground-water source. It was acknowledged that the actual split may change from irrigation season to irrigation season depending upon the surface water supply and that no record is kept of supplemental ground water use. This analysis resulted in approximately 63% of mixed-source lands within the study area being assigned to a ground-water source (ESPAM Design Document DDW-017).

The operation of the Fortran recharge tool implicitly adjusts for changes in ground-water use on mixed-source lands, by the process used to calculate net recharge. Within the tool, full irrigation requirement (consumptive use minus precipitation) is applied to all irrigated lands as an aquifer extraction. On lands with surface-water supplies, net surface-water application is applied as aquifer recharge, offsetting the required irrigation extraction. For each stress period and each surface-water irrigation entity, the net depth of surface-water application is calculated based on the diversion and return data for that stress period. The application depth is based on the full acreage of surface-water only parcels and a portion of the acreage (based on the source fraction described above) of mixed-source parcels. Then, within each model cell, the stress-period-specific application depth is applied as an aquifer recharge. The applied water is pro-rated to mixed-source and surface-water-only parcels based on the source fraction. Where application exceeds irrigation requirement (surface-water-only parcels) a net recharge is inferred. Where irrigation requirement exceeds application (mixed-source parcels) a net withdrawal is inferred. On mixed-source parcels, in years with high surface-water supplies, the difference between irrigation requirement and surface-water

supply is small and small amounts of net ground-water pumping on these mixed lands are represented in the model water budget. When surface-water supplies are low, the difference is large and large amounts of ground-water pumping are represented.

Reduction for Non-Irrigated Inclusions

The irrigated lands shown in Figure 25 represent the spatial extent of irrigated areas. However, some portion of these areas is actually non-irrigated areas such as roads, homes, rock piles and canal banks. During the estimation of recharge and discharge, the actual square footage of irrigated area in each model cell is reduced by a factor which accounts for these non-irrigated inclusions. For the ESPAM calibration period, irrigated areas were reduced by 12%. The reduction factor was determined using a GIS analysis of individual parcels mapped by IDWR as part of the Snake River Basin Adjudication (Norquest, 2002). ESHM Committee members agreed that 12% was a reasonable estimate for reduction in irrigated area.

In the GIS/Fortran Recharge Tool (described in Appendix B), the capability exists to specify a reduction factor for each model stress period by application method. This enables the user to reflect a potential different reduction factor for sprinkler versus gravity irrigation for each time period. For the ESPAM calibration, the consensus of the ESHM Committee members was that the estimate of non-irrigated inclusions derived from IDWR GIS data, which showed no statistically-significant difference between sprinkler and gravity application, represented the best available estimate for the irrigated lands reduction factor.

Aggregation of Canal Companies into Surface Water Entities

There are more than 100 surface water irrigation companies and numerous private surface water irrigators within the ESPAM boundary. Many of these irrigation companies share common acreage. In order to treat all surface water irrigated areas in a consistent manner, these surface water irrigation companies are aggregated into a smaller number of 'irrigation entities.' The aggregated irrigation entities more accurately reflect the delivery of surface water to the irrigated areas by maintaining a level of resolution consistent with available diversion and return flow data.

A similar surface water irrigation company aggregation was performed for the original UI/IDWR SRPAM model. Because GIS software was not available at that time, the irrigation company aggregation was a more difficult process and took much longer to complete. The earlier aggregation resulted in approximately 172,000 acres throughout the plain being assigned to an un-named surface-water entity.

For the current study, the process of aggregating surface water irrigation companies entailed evaluating each irrigation company to identify the point of diversion from the river and the likely corresponding irrigation return flow location. Adjacent irrigation companies were then examined for similar characteristics, including irrigation practice, points of diversion, common conveyance, location of irrigation return flow, soil type, water right priorities, common drainage area, and previous aggregation in the earlier UI/IDWR SRPAM model. If adjacent irrigation companies did not have any significant differences from one another, they were aggregated into the same irrigation entity to maintain a level of irrigation company resolution consistent with the resolution of the diversion and return flow data.

Most private water rights within the model boundary were aggregated with the organized irrigation companies. The private rights that were not aggregated with adjoining entities are: Camas and Beaver Creek (Basin 31), Birch Creek and Medicine Lodge Creek (Basin 32), and Little Lost River (Basin 33). The private rights in these three basins were aggregated separately from each other and from the irrigation companies because of different practices and water supply than the organized companies. Source of irrigation water was determined from IDWR adjudication data (see ESPAM Design Document DDW-017).

Three irrigation companies in the Mud Lake area, including Jefferson Irrigation Company, Monteview Canal Company Incorporated, and Producers Irrigation Company, do not use surface water for irrigation. These companies use off-site ground water pumping and were aggregated as a surface water irrigation entity for model purposes. With ordinary ground water irrigation, it is assumed for modeling that the pumping and the recharge occur within the same model cell. This is not the case for the aforementioned canal companies. The wells used to obtain water are miles from the place of use and conveyed by a canal. Therefore, in the model, the pumping and recharge would occur in different model cells. Because many irrigation companies that use off-site ground water pumping co-mingle the pumped ground water with the surface water in the canals, the ground water withdrawal was treated as a point extraction assigned to the model cell. This withdrawal, or volume extracted, was added to the surface water diversions for the respective irrigation entity. When water master records were not available to determine the amount of ground water pumped, estimates were made. For

the three companies mentioned, the surface-water component is set to zero, since there is no surface-water supply.

The aggregation process resulted in 43 irrigation entities (Table 10). These 43 entities were assigned an identification number (for use by the GIS/Fortran Recharge Tool) and a descriptive name. Descriptive names were created by choosing the largest (by area) organized irrigation company in the entity, and adding on to that name the number of organized companies aggregated to create that entity. For example, aggregated entity IESW16, named "Egin 2", consists of two organized companies, Egin Bench Canals Inc. and St. Anthony Union Canal Company, of which Egin Bench Canals Inc. is the larger (by area), of the two companies. (Note that a mid-project recombination of some of the entities to correspond to new return-flow data resulted in some entities whose names may violate the "biggest company" naming convention.) Figure 30 shows the final set of irrigation entities. For a more detailed description of the aggregation of canal companies into irrigation entities, the reader is referred to ESPAM Design Document DDW-008.

Delineation of Ground Water Irrigation Polygons

This section describes the designation of portions of the study area into "Ground Water Irrigation Polygons" for the purpose of recharge calculation. The withdrawals associated with irrigation from ground water are a negative recharge and are calculated based on adjusted ET and precipitation. The ET adjustment factor is applied according to the geographic location of the irrigated land being calculated and the method used to apply irrigation water. ET adjustment factor and application method parameters for

irrigation from ground water are carried as attributes of the ground water irrigation polygon map.

The goals in constructing the ground water irrigation polygon map were to adequately represent known differences between geographical areas and management practice and to minimize the number of unique ground water polygons (to reduce data management concerns and recharge tool run times). Because these ground water irrigation polygons are only used for assigning ET adjustment and application method parameters for recharge calculation, no requirement was made that polygons be contiguous areas. Similarly, the ground water irrigation polygons assigned for recharge calculation are not based on current ground water management areas or measurement districts, nor is it contemplated that these polygons would form the basis for any administrative boundaries or decisions.

Because both ET adjustment factor and percent sprinkler application are driven largely by cost of water, and because the primary cost of ground water is the energy cost for lifting water out of the ground, depth-to-water was used as the basis for delineation of the polygons. Relative to the range of depths on the plain, water level changes since 1980 are minor, so a single water table map was deemed adequate for the delineation. Figure 31 shows the depth-to-water map used for the analysis, digitized from a paper map created by Lindholm and others (1988).

Pumping lift was hypothesized to influence the cost of water and crop production and consequently the intensity of management. Regional variations in cropping patterns and climate throughout the Snake Plain were also considered to be factors in management intensity. Intensively managed crops are expected to approach the ideal values of crop

coefficients. Poorly managed crops are expected to exhibit less evapotranspiration. Depth to water (pumping lift) provided a basis for dividing the Snake River Plain into GIS polygons. These polygons were then subdivided based on location within the plain. That is, if a single polygon represented a depth to water of 100 to 200 feet, this polygon would be divided into two units if this depth range existed in both the southwest and northeast portions of the plain. The final GIS polygons are presented in Figure 32. The central portion of the plain is absent of irrigation which is identified as polygon IEGW600 in Figure 32.

The Mud Lake area and the U.S. Bureau of Reclamation project known as the "A & B Irrigation District" were the first large-scale applications of ground water on the plain (Goodell, 1988). These developments pre-dated the widespread use of sprinklers, while most other ground water development post-dated the use of sprinklers. Field observations show that the Mud Lake area still has a different mix of application method relative to other ground-water areas. The same is true of the A & B Irrigation District (Temple, 2002). For this reason, these two areas were partitioned into their own, unique ground water irrigation polygons.

Method of Irrigation Application

An analysis was done to identify what percentage of irrigated areas has been irrigated by sprinkler versus furrow irrigation throughout the simulation period. Because actual evapotranspiration may be affected by the type of application system used (as well as other factors), and because changes in application system type (e.g. conversion from gravity to sprinkler) have occurred during the period of the study, a method for identifying application method and describing changes was required. Identification of the

method of irrigation application on each parcel of land allows application of ET adjustment factors for deviations from predicted ET which are associated with sprinkler or furrow irrigation.

Previous modeling efforts have not included an ET adjustment factor, so there has not been a need to identify application method. Neither Garabedian (1992) nor IDWR (1997a) explicitly referred to consideration of application method in irrigation calculations. Goodell (1988) used application method to derive discharge pressure parameters for pumpage calculations, but not for recharge or ET calculations. IDWR (1997a) adjusted for non-irrigated inclusions based on a distinction between ground water and surface water, but examination of maps indicates that it is likely the difference is actually driven by application method, and water source was used as a surrogate.

Available data included Geographic Information Systems (GIS) electronic maps that delineate the irrigated lands in the study area in 1982 and 1992 as sprinkler or gravity irrigated (IDWR 1982, 1992). The Natural Resource Conservation Service National Resource Inventory (NRI) includes a report of a statistical sample indicating percent of irrigated acres using pressurized (sprinkler) systems by 8-digit Hydrologic Unit Code area or by Major Land Resource Area (MLRA) (NRCS, 1997). NRCS also classifies drip irrigation as a pressurized system but this is such a minor practice within the current calibration period that it is neglected here.

Since the 1982 and 1992 GIS maps represent the most certain data, and the data with the best spatial resolution, these maps were used as the primary data source. The NRI data are statistically-based, and quantify percentages, so they were used to establish overall percentages for 1987 and 1997.

Initial tables of sprinkler percentage for each irrigation entity or polygon were constructed for 1982 and 1992, using GIS and the 1982 and 1992 maps. From the irrigation entity and water source maps (Figures 29, 30 and 32), all ground-water-irrigated and mixed-source lands in each ground water polygon, and all surface-water-irrigated and mixed-source lands in each surface-water entity were identified using GIS software. These maps were intersected with the application method maps to produce maps of irrigated lands with appropriate water source, by application method, by ground water polygon or irrigation entity. The total area of each method, within each entity, was used to calculate a sprinkler percentage for each entity or polygon. This process was done for both 1982 and 1992. The result was a table of values, having a unique sprinkler percentage for each irrigation entity or polygon, for the break-point years 1982 and 1992.

The NRI data were used as a secondary source, to determine sprinkler percentages for 1980, 1987, 1997 and 2000. Sprinkler percentages for other years were linearly interpolated between these values. Table 11 lists the ratio of area under sprinkler application for each ground-water and surface-water entity for each of the years for which data were available.

The complete table used in model calibration includes values for each stress period and is presented in Appendix A, Table A-5. Figures 33 and 34 show the spatial distribution of the sprinkler fractions for the years 1980 and 2000 by surface water irrigation entity and by ground water polygon, respectively.

Surface Water Irrigation

Net recharge incidental to surface irrigation occurs when more irrigation water is applied and remains on the field than the crop demands. As noted in Equation 8, field

delivery is the volume of water diverted minus canal leakage and irrigation return flows. Net recharge to the aquifer is estimated as the field delivery plus precipitation, less adjusted ET (Eq. 9). Precipitation and adjusted ET have been discussed in previous sections. The following sections discuss estimation of irrigation diversions, return flows conveyance loss and the estimation of net recharge due to surface water irrigation.

Irrigation Diversions

In order to effectively and accurately estimate percolation to the aquifer due to surface water irrigation, irrigation diversions from the river must be estimated with the highest possible degree of accuracy. Irrigation return flows to the river and evapotranspiration are also components of calculating percolation from surface water irrigation.

For Snake River diversions, two sources of data were considered for use in estimating surface water irrigation diversions. The first source is irrigation diversion and return flow 'raw' daily data from the water districts, and the second source is 'processed' monthly data that is used in the IDWR Reach Gain/Loss Program. For consistency with the IDWR Reach Gain/Loss Program estimates of reach gains that were used for model calibration, the 'processed' monthly data were used to estimate irrigation diversions.

The diversion data which are used as input to the IDWR Reach Gain/Loss Program were assigned to appropriate canal companies. The diversion data for each canal company were aggregated into the appropriate surface irrigation entity by use of a Microsoft Excel spreadsheet, described below. More information about the estimation of Snake River surface irrigation diversions is available in ESPAM Design Document DDW-012.

Data for surface water diversions from sources other than the Snake River were primarily available from watermaster records. The actual data were obtained from various sources, including electronic files from Idaho Department of Water Resources (2001), paper and microfiche watermaster records (IDWR, 2002b), and other sources. In the case of watermaster reports, data were generally available as annual summaries. Monthly fractions were determined by hand calculation from a sample of microfiche or paper copies of daily watermaster records, and applied to annual data. The irrigation entities which use some non-Snake River diversions are IESW005, IESW007, IESW008, IESW025, IESW029, IESW037, IESW051, IESW052 and IESW054 (see Table 10). A complete description of the non-Snake River diversion data is available in ESPAM Design Document DDW-024.

Using both the Snake River and non-Snake River diversions and the aggregated surface water irrigation entities, a spreadsheet was created in Microsoft Excel to estimate surface water irrigation diversions for each surface water irrigation entity. This spreadsheet was also used to perform the calculations to estimate irrigation return flows to the Snake River, using monthly diversion data and return flow percentages (see section on Irrigation Return Flows).

The spreadsheet contains separate worksheets for each irrigation entity. Each worksheet contains the diversion data and return flow factors for all of the irrigation companies and private irrigators which comprise the associated irrigation entity.

Irrigation return flow factors (discussed in the following section) are applied to the respective diversion data on each worksheet of the spreadsheet file. The monthly diversions and returns for each canal company and private irrigator are summed to yield

the monthly diversions and returns for the irrigation entity. Table A-6 lists the diversion volume for each irrigation entity for each stress period.

Irrigation Return Flows

Forty-six irrigation returns were measured as part of this study. The sites were selected and measured in a joint effort between Idaho Power and the U.S. Geological Survey, with oversight from the ESHM Committee. Irrigation return flow locations on the Snake River below American Falls Reservoir were suggested by IDWR to match the sites used in a study conducted in 1985-86. For the upper Snake River, candidate sites were identified from a video taken during a helicopter flight over the Snake River above American Falls and the Henrys Fork.

The site selection was verified through field work. Each selected site was assigned a standard eight digit USGS gage identification number. Pressure transducers with data loggers were installed at each site and irrigation return flow data were collected for the 2002 and 2003 irrigation seasons. The reader should note that both 2002 and 2003 were extraordinarily dry years, so the measured return flows from these two seasons may not be representative of other years. However, very little measured return flow data exist for the ESRP. Table 12 lists the site name, location (lat/long) and USGS identification number for each measured site. Maps of site locations above and below American Falls are included in Figures 35 and 36, respectively.

Each return flow was assigned to an appropriate irrigation entity as defined in ESPAM Design Document DDW-008. The assignment was accomplished using the maps of irrigation entities (Figure 30) and return flow locations (Figures 35 and 36). The assignment was made based on location, land elevations and canal locations. Some of the

returns on the Henrys Fork serviced more than one irrigation entity. The number of return sites per entity ranged from as many as ten for IESW032 (Twin Falls Southside) to one site shared by three irrigation entities on the Henrys Fork of the Snake River. Several entities were grouped together for the purpose of return flow calculation rather than try to parse the amount diverted from a single diversion between two or more entities. This procedure resulted in aggregating the returns and diversions into ten unique groups that were used to calculate the return flow lag factors. Table 13 lists the grouping of irrigation entities used to estimate return flow percentages. Diversions were summed for each of the return flow groups. Using measured return flows and an estimate of the volume of un-measured return flows for each group, a total percentage of irrigation return flow was estimated. This percentage was used to reduce the total diversion by the fraction of return flow to estimate how much water to apply to lands irrigated with surface water. Figure 37 shows the net irrigation diversions (minus return flows) and return flows for each year.

It should be noted that the Milner-Gooding Canal is used to deliver Snake River water directly to irrigation and also to deliver Snake River water into the Big Wood River, for downstream re-diversion by other canals. The data in their native format include this water as a Snake River diversion to the Milner-Gooding Canal and also as a Big Wood River diversion to other canals. To prevent this from causing double-counting of surface water applied to land surface, deliveries from the Milner-Gooding Canal directly into the Big Wood River were treated as return flows in the net-diversion calculations for entity IESW007. Due to this adjustment, the variability of the return-

flow values shown in Figure 37 is somewhat dampened and the magnitude is somewhat amplified.

Irrigation diversions and return flows are also used for the estimation of river gains and losses, which are discussed in a later section. In addition to the return percentage, the measured return flow data were also used to calculate the lag time of return flows in support of the estimation of river gains and losses. Examination of typical hydrographs of surface water returns versus diversion records indicates that there is a time lag between the timing of the diversions and the timing of the returns. A typical return flow hydrograph shows an increase as the irrigation season progresses. The diversions will remain constant or actually decrease during this same time period. The increase is likely due to increased returns as the fields and canals become saturated.

This phenomenon was dealt with by applying the concept of lag factors. Lag factors are the portion of the diverted water which returns to the river in each month following diversion. The lag factors are a time series of ratios. For example, a typical lag factor series might be (.01, .03, .07, .02, .01). Applied to a single month's diversion, this would mean that 1% of the diverted water returns in the first month, 3% in the second month, 7% in the third month, etc. By applying the lag factor series to the monthly diversions, the net diversion and return flow for each model stress period can be calculated. The sum of the lagged factors equals the total return percentage used in calculating net diversions.

Up to twelve lag factors could be used but more than five were never needed to obtain a "best fit" to the measured return flow data. The lags were estimated using an Excel spreadsheet. Measured return flow hydrographs were compared with predicted

return flow hydrographs. The return flow lag factors used to generate the predicted return flow hydrographs were adjusted until a reasonable match was obtained between predicted and measured hydrographs. This process was repeated for each of the ten groups of irrigation entities. Table 14 shows the final return flow lag factors for each of the ten groups of irrigation entities. ESPAM Design Document DDW-005 describes the estimation of return flow lag factors in detail. ESPAM Design Document DDF-007-2002 summarizes the measured return flow data for the 2002 season.

Irrigation entities for which there were no measured return flows were correlated with one of the ten groups of entities based on a) magnitude of diversions, b) method of irrigation application, c) regional similarity and d) similar crop mix. The return flow lag factors for the correlated entity were applied to the entity for which there were no measured return flows. These lag factors were entered into the input data sets for the IDWR Reach Gain/Loss Program which is used to estimate monthly Snake River gains and losses.

During model calibration, comparison of net model recharge with measured hydrographs indicated that there was too much water being applied to the model in the latter ten years of the calibration period. Inspection of the data indicated that the first ten years of simulation showed generally high water levels, corresponding to wet hydrologic conditions and high rates of recharge. This was followed by a decline in simulated water levels and then by a return to the high levels simulated for the first wet period. Observed water levels showed this same general trend, but in the second ten-year period, water levels did not quite return to the levels observed during the first ten-year period. The discrepancy between these two temporal patterns suggested that estimated net recharge

was too high during the latter part of the calibration period. After much discussion, the ESHM Committee agreed that applying an increase in irrigation returns would serve the purpose of reducing the net recharge. This adjustment was made to help balance the water budget and did not imply any knowledge of the trends of irrigation return flows over time. Irrigation return flows have largely been un-measured on the ESRP despite the fact that return flows are such an important element of the water budget. The current study was limited to using measurements from the 2001 irrigation season and some limited measurements which were made in the 1985-1986 seasons. Efforts to measure return flows on the ESRP should be continued into the future so that the return flows can be better characterized and the new information can be incorporated in future modeling and calibration efforts. Table A-7 lists the return flow volume for each irrigation entity for each model stress period.

Conveyance Loss

Some of the water lost from irrigation is seepage from canals and ditches. This water is not available for irrigation and therefore neither available for crop evapotranspiration (ET) nor for recharge associated with irrigated agricultural fields. However, the leakage is still a component of recharge associated with irrigation activity. Seepage from canals can be an important source of aquifer recharge. Long canals in porous soils can lose 40% or more of the water diverted from the source (Chavez-Morales, 1985). In Idaho's climate, virtually all of this loss is associated with leakage to the aquifer (Dreher and Tuthill, 1999). Canal leakage can be represented by explicitly identifying leakage rates and locations. Or, a simplified approach can be taken by

assuming that canal leakage is spatially distributed across the irrigated lands served by the canal.

Most canal systems have a large main canal or canals, supplying secondary laterals. These in turn supply individual farm ditches. Because size, construction, and maintenance of laterals and farm ditches are highly variable, estimating leakage on these secondary conveyances is difficult. Alternate wetting and drying can damage the "skin of sediment and biological slime" that helps seal canals. Smaller channels have more frequent drying cycles, and have more wetted perimeter relative to total flow capacity, so losses in these ditches are often higher than in main canals (Hubble, 1991). These laterals and farm ditches are widely distributed across irrigated areas. For these reasons, the simplified approach often closely reflects reality.

In prior Eastern Snake Plain models, a mixed approach has been taken. Garabedian (1992) treated three canals - Aberdeen-Springfield (95,000 AF/year), Milner-Gooding (97,000 AF/year), and Reservation (11,000 AF/year) - as leaky. IDWR (1997a) treated only the Milner-Gooding Canal as leaky and attributed 146,000 AF of annual leakage to that canal. In both models, all other canal leakage was assumed to have spatial distribution similar to the spatial distribution of irrigated lands.

In the ESPAM, Northside, Milner-Gooding and Aberdeen-Springfield canals are represented as leaky. These are high-volume canals with significant leakage along reaches that do not correspond with the irrigated places of use. Figure 24 shows a map of the canals which are represented as leaky in the ESPAM. Some of the canal reaches shown in Figure 24 are sub-reaches of the three canals mentioned above.

Seepage is a function of the hydraulic conductivity of the bed material, the wetted perimeter, and the head (depth of water) in the canal. Because wetted perimeter and head can vary with flow, there is conceptual justification for using a percentage of flow to describe leakage. This is sometimes done in irrigation system assessment (Hubble, 1991) and has been used in aquifer modeling (Booker and others, 1990). Canal leakage can also be represented as a specified rate (volume per time), which has also been used in ground-water modeling efforts (Garabedian, 1992).

Because both specified-rate and percentage-based leakage rates are supported in the literature and can be justified conceptually, either was a candidate for use in the ESPAM. Since a diversion rate partially controls seepage (apparent from the Chavez-Morales (1985) data), and since a percentage calculation guarantees that there will never be leakage calculated in a period without diversions, a percentage-based method was selected for the ESPAM. Canal leakage was applied to linear GIS features representing leaky sections of canal. The GIS/Fortran Recharge Tool accommodates multiple leaky canal sections per irrigation entity, each with a unique leakage rate. The leakage rate can also be varied with time. Locations and leakage rates were assigned based on interviews with canal company personnel and results of previous studies. Some laterals of the Northside Canal were added in response to comparisons between model-predicted hydrographs and observed hydrographs at some wells, during early stages of calibration. For the Northside and Milner-Gooding canals, a constant leakage rate was used throughout the study period. For the Aberdeen-Springfield canal, unique values were assigned to each stress period based on canal-company data (Howser, 2002).

Varying canal seepage within a season may allow a better fit to measured heads in wells. While it is acknowledged that intra-season variation in canal leakage may occur, and that these differences may propagate into aquifer heads, data were not available to adequately represent these conditions for the calibration period. Leakage rates were based on interviews with canal personnel and checked against values published by Garabedian (1992) and IDWR (1997a). Because imprecision in calculating canal leakage affects only the spatial distribution and not the total amount of recharge, and because of the danger of introducing error by synthesizing data, canal leakage for the model calibration period was estimated as a constant percentage of diversion volume within each irrigation season. To allow for future testing of various scenarios, the GIS and Fortran components of the recharge tool allow unique canal leakage percentages to be applied to each stress period. The data available from the Aberdeen-Springfield Canal Company are annual volume totals, so the fractions calculated were based upon annual volumes. Table A-8 lists the canals, the assigned irrigation entities and the seepage percentages used during the simulation for each of the canals.

Net Recharge from Surface Irrigation

Net recharge due to surface irrigation is calculated in the GIS/Fortran Recharge Tool (Appendix B). The GIS component of the tool prepares text data files containing a) a mapping of surface water entities to model cells within each entity's service area, b) reduction factors for non-irrigated inclusions, c) ET and precipitation for each model cell for each stress period, d) ET adjustment factors, e) diversion data, return flow percentages, canal leakage percentages and sprinkler proportion for each model stress

period for each surface water irrigation entity and f) off-site pumping volume delivered for irrigation.

For each model cell, for each stress period, the GIS/Fortran Recharge Tool calculates the net recharge due to surface water irrigation according to Equations 8 and 9. The net recharge from surface water irrigation is added to other estimated recharge and discharge (for example, ground-water withdrawals in the same model cell). Figure 37 shows the net recharge due to surface water irrigation for every year of the calibration period. Inspection of Figure 37 shows that there is approximately a 2 million-acre-ft variation in net recharge due to surface water irrigation between the highest and lowest years of the 22-year calibration period. This reflects the great variation in natural water supply. This also reflects the important role that incidental recharge to the aquifer from surface water irrigation plays in aquifer recharge.

Ground Water Irrigation

Net discharge from ground-water irrigation is estimated as consumptive use (ET) offset by available precipitation (Eq. 10). ET adjustment factors are applied to the estimated evapotranspiration based on source of irrigation water and method of application. No difference was found between ET for ground-water or surface-water irrigation. Sprinkler irrigation was determined to consume approximately 5% more water than furrow irrigation (see ESPAM Design Document DDW-021). Figure 37 shows the net extraction due to ground-water irrigation. As can be seen in Figure 37, a relatively constant 2 million AF annually is applied to approximately 1.1 million acres of ground-water irrigated land. This reflects the relatively constant rate of ET (see Figure 27). Much of the variation in net extraction due to ground-water irrigation (a variation of

approximately 900,000 AF) is arguably driven by variation in precipitation (approximately 1,200,000 AF variation). Figure 38 shows the spatial distribution of the net extraction due to ground-water irrigation averaged for the 22-year model calibration period.

Tributary Underflow

Groundwater contributions from tributary basins, or tributary underflows, were estimated for the new model based on tributary underflow estimates published in Garabedian (1992). The Garabedian estimates were adjusted in tributary basins where the ESPAM aquifer boundary differed from the Garabedian aquifer boundary. As part of the water budget balancing process, all of the tributary underflow estimates were scaled by a factor of .97 (a net 3% reduction). Table 5 lists the average annual tributary underflow values used for ESPAM.

Recognizing that tributary underflow varies seasonally and from year to year, the average annual ESPAM tributary underflow values were scaled using normalized annual values based on measured discharges at Silver Creek. Silver Creek was selected because a) it is almost entirely spring-fed and sits on bedrock, b) there is a long-term gage on Silver Creek and c) the flows in Silver Creek reflect spring discharge from a basin which is similar to many of the Snake Plain aquifer tributary basins from the standpoint of land use, precipitation, and elevation. It is believed that flow of Silver Creek is more seasonally variable than underflow in the tributary valley. Therefore, the variation of Silver Creek discharge was dampened by 2/3 to decrease the amplitude of variation. Table 15 lists the non-dampened and dampened normalized flows for Silver Creek for each year of the ESPAM calibration period. The average annual tributary underflow

discharge for each tributary basin was multiplied by the dampened Silver Creek normalized flow for each time period, yielding the contribution from each tributary to the ground water model for each stress period. While it is acknowledged that there will be intra-year variations in flow, lack of knowledge about the basin-to-basin differences in the timing of peak flow dictated shaping underflow on a year-by-year basis (Table 5). ESPAM Design Document DDW-004 describes the estimation of tributary underflow for the ESPAM in more detail.

Recharge on Non-Irrigated Lands

This section discusses calculation of two spatially-distributed components of the aquifer water budget; recharge from precipitation on non-developed lands and spatially-distributed recharge and discharge from land uses that comprise a small fraction of the study area. These minor-use areas are dry farms, cities, and wetlands.

Precipitation on the plain is approximately 6.7 million AF per year, with 80% of this falling on non-developed lands. Garabedian (1992) estimates that precipitation on non-developed lands produces 700,000 AF of recharge per year, which equals approximately 15% of the magnitude of irrigation recharge. It is the component of recharge to which Garabedian assigns the most uncertainty. The other land uses, dry farms, cities, and wetlands, represent minor components of the water budget, with a combined net effect of about 160,000 AF per year (calculated from data reported by Goodell, 1988).

Recharge on Non-Developed Lands. A method was developed for estimating recharge from precipitation using GIS grid maps of monthly precipitation (Daly and others, 1998) and thickness and texture of soil coverage (Figure 25). The developed

method is suggested by Rich (1951). Rich studied basins which, unlike the Eastern Snake Plain, had a component of surface discharge. His relationship actually described total basin yield, but it is simplified here to represent recharge, since runoff that does occur on the plain collects in depressions where it also recharges the aquifer. The equation is:

$$\text{Recharge} = K * (\text{Precipitation})^{N} \qquad \text{(Eq. 12)}$$

where K is an empirical slope parameter and N is an empirical exponent that introduces curvature into the relationship.

Rich applied this formula to annual precipitation. The formula presumes that with less precipitation, most of the precipitation is intercepted by various mechanisms (leaf interception, depression storage, soil moisture storage, evaporation, etc.) and that with increasing precipitation, more of the precipitation is available for infiltration. Parameters K and N can be adjusted to shape the calculated recharge curves. However, knowing the actual recharge from precipitation on non-irrigated arid lands is very difficult (Gee, 1988). Attempts to use a water balance to determine the non-irrigated recharge are frustrated by the fact that another large component of recharge, tributary basin underflow, is also poorly defined. Consequently, parameters K and N were initially calibrated to match previous results. ESPAM Design Document DDW-003 contains a detailed explanation of the estimation of recharge on non-irrigated lands.

Estimates of recharge depth from Equation 12 were performed for three soil classifications based largely on soil thickness. These calculations employed monthly estimates of precipitation. Precipitation during November through February was summed into the February value to represent snowmelt. These calculations were performed

external to the GIS component of the recharge program but were input to the Fortran component of the recharge program as monthly recharge depths. A fourth soil classification was used to represent the minor land uses (cities, wetlands and dry farms).

Within the Fortran component of the recharge program, the recharge depths from non-developed land were multiplied by the non-irrigated land in each cell. Non-irrigated land was determined as the difference between the area of a cell and the irrigated area within the cell. Monthly non-irrigated recharge values were summed to estimate recharge in each stress period. Figure 39 illustrates the areal distribution of non-irrigated recharge averaged for the 22-year calibration period.

Recharge on Minor Land Use Types. Several minor land use types were identified and recharge on these areas was handled separately. The categories of minor land uses which were identified were: dry farm, water and wetlands and cities and industrial areas. Table 16 lists the minor land use types, the acres represented by these types and the recharge rate. On dry farms, the recharge rate was presumed to be zero. Discharge on wetlands was presumed to be three feet, less precipitation. Discharge for cities and industrial areas, which is attributable to parks and lawn watering, was presumed to be 1.2 feet/year. The discharge from wetlands and cities is represented in Figure 39 as negative recharge. These minor land uses are discussed further in Contor (2002).

Fixed Point Pumping

Fixed point pumping (or recharge) represents an impact that occurs at a single point and does not enter into any other recharge calculation. Negative values are applied directly as an extraction from the model cell that contains the point, and positive values

are applied as a direct injection. Fixed point pumping was used to represent the following practices: a) pumping where the pumped water is added to a natural water body to augment the surface water supply and the same water is counted as a diversion from that surface water body, b) recharge corrections for deficit irrigation on the Richfield tract and c) recharge correction for wetlands. Table A-9 lists the model cells where fixed pumping is represented.

Irrigation Wells. In the ESPAM, certain irrigation wells are treated as fixed-point pumping because the pumped water is delivered to a natural water body and is included in the water master reported diversion volume of water diverted for irrigation from the water body. One group includes wells known as "exchange wells," which pump water into the Teton River or the Snake River. Their volumes are included as diversions within the diversion data files from the IDWR planning model (see ESPAM Design Document DDW-012). The other group of fixed-point wells includes the wells that deliver water into Mud Lake or Camas Creek in Jefferson County, for diversion to irrigation entity IESW029. The volume of water pumped from these wells is included within the diversion volumes reported by Water District 31 (see ESPAM Design Document DDW-025).

The spatial location of the "exchange wells" class of fixed points was obtained from GPS data or public land survey legal descriptions supplied by Water District 01 (Madsen, 2000; Olenichak, 2003). Figure 40 shows the location of these exchange wells.

The GIS points for the Mud Lake fixed points and the offsite ground-water pumping wells were placed to represent groups of physical wells within small local areas. The actual locations of the physical wells were obtained from IDWR GPS data (IDWR,

1999) and aerial photography. Figure 41 shows the fixed points in the Mud Lake area, relative to the model grid, observation wells, and physical pumping wells.

Pumping volume for the "exchange wells" fixed points was obtained from Water District 01 annual reports (Water Distrtict 01, 2003). These data are complete for the entire calibration period. The annual reports include monthly pumpage volume for each well that is active in a given year. The gross pumping volume for the "Mud Lake" fixed points was obtained from Water District 31 data, as described in ESPAM Design Document DDW-025. To apportion the Mud Lake volume to individual points, the number of wells per model cell was adjusted to better reflect field observations of relative production of individual well groups. The fraction of the total volume assigned to each point was apportioned to the adjusted number of wells, as shown in Table 17. Any uncertainty in apportionment represents imprecision in the spatial distribution of discharge, but not an uncertainty in the water budget.

Richfield Tract Recharge Adjustment. An adjustment was made on the Richfield tract to account for deficit irrigation conditions. Because most irrigated areas with limited surface-water supplies have supplemental wells, the GIS/Fortran Recharge Tool automatically presumes supplemental ground-water pumping whenever surface-water supplies are inadequate to meet consumptive use demand. For some stress periods this is an inappropriate calculation for irrigation entity IESW007 (in the Richfield area), since deficit irrigation occurs without the opportunity for supplemental ground-water pumping. This is corrected by applying an offsetting volume to a deficit-irrigation class of fixed points, in those cells where deficit irrigation occurs without supplemental ground water. This correction is explained in further detail in ESPAM Design Document DDW-003.

Deficit irrigation correction volumes were determined by identifying cells without groundwater where net irrigation from surface-water irrigation was zero or negative. Using a spreadsheet, a correction volume was calculated to offset the indicated negative recharge.

Wetlands Correction. During model calibration, the need for a correction for wetlands became apparent. As described in ESPAM Design Document DDW-003, Recharge on Non-irrigated Lands, a correction was required for model cells that contained both wetlands and irrigated lands. The GIS/Fortran Recharge Tool applies the cell-average non-irrigated recharge rate to the non-irrigated lands within each model cell. When part of the cell is irrigated and part is wetlands, the cell-average rate is biased by the non-irrigated-recharge rate associated with the soil type on the irrigated lands. This bias was corrected by applying an offsetting volume to a wetlands class of fixed point pumping in those cells containing both irrigation and wetlands. Wetlands correction point volumes were determined by calculating the correct non-irrigated recharge in individual cells with both wetlands and irrigation, and comparing the volumes to the volumes calculated by the GIS/Fortran Recharge Tool.

Figure 42 illustrates fixed points used to represent the wetlands and deficit-irrigation correction points. Table 18 lists the total adjustment to recharge for each stress period for each category of fixed point well.

Off-Site Ground Water Pumping

Offsite ground water pumping refers to irrigation pumping that is conveyed to a distant location for application to irrigated lands. It must be accounted as a withdrawal from the model cell that contains the well and as applied irrigation water to the model

cells that contain the irrigated lands. While physically this is the same process that is represented by fixed-point pumping for the exchange wells and Mud Lake wells described above, the accounting difference is that offsite-pumping volumes have not been included in a water-master reported diversion volume. They must be added to diversions within the recharge calculations. In this modeling effort, wells in Jefferson County that supply water to irrigation entity IESW044 are represented as offsite ground water pumping. While irrigation entities IESW001 (A & B Irrigation District) and IESW018 (Falls Irrigation District) also pump ground water into canals for conveyance to places of use, their wells are distributed approximately uniformly across the irrigated service area, similar to other ground-water irrigated areas within the study area. There is not a need to spatially separate the extraction and recharge associated with irrigation.

In the Fortran component of the recharge tool, the pumped volume from the offsite ground water pumping wells is removed from the cells in which the wells are located, and added to diversions for IESW044. The entire pumped volume is included in the irrigated-lands recharge calculation as a contribution towards recharge. Volume-for-volume, any over-estimate in pumping becomes an over-estimate in irrigated-lands recharge, and any under-estimate in pumping becomes an under-estimate in recharge. The inaccuracies balance, so that the only consequence of an inaccuracy in estimating pumping volume is an inaccuracy in spatial distribution of discharge and recharge. The region in which this practice occurs is distant from the Snake River so these potential inaccuracies have a low impact to predictions near the river.

An initial pumping estimate of 4 AF/ac/yr comes from experience of the North Water Measurement District for water years 1997 through 1999. This appears reasonable considering ET, precipitation rates and irrigation and conveyance efficiency.

The lands in IESW044 are aggregated from three irrigation companies; Jefferson Irrigation, Monteview, and Producers Canal Companies. Three of the offsite points are associated with the Jefferson lands, three with the Monteview lands, and two with the Producers lands. Figure 43 shows the location of the off-site wells. Based on the original GIS shapefiles (see ESPAM Design Document DDW-008), the 2000 irrigated lands map was clipped to show irrigated lands in each of the three companies. The acreage of these lands was multiplied by four feet to determine a gross pumpage volume for each company, then divided by the number of represented off-site wells to obtain an annual volume per well. The annual volume was distributed among the months according to a crop-weighted average monthly ET from U.S. Bureau of Reclamation (2003) Agrimet data for 2000.

To scale pumpage to reflect year-to-year differences in ET, an index was constructed for each year 1980 through 2000 using revised ET values (Allen, 2002) for Hamer, Idaho (the nearest weather station with a full record). The ET index is a factor that relates ET for each given year to the long-term average ET. It is multiplied by the derived average monthly pumpage to give a monthly pumpage adjusted for the individual year's climatic regime.

Because the Monteview AGRIMET station did not start operation until 1997, the Hamer NOAA station was used to calculate the index for years up through 2000. For each of those years, the index was estimated as the ETr for the specific year divided by

the average ETr. Because the revised ETr for the Hamer NOAA station did not include a value for 2001, the 2001 index was derived from Monteview AGRIMET data. The results are summarized in Table 19. ESPAM Design Document DDW-026 contains more details regarding the estimation of off-site ground-water pumping. Table 20 lists the represented pumping in each model stress period for the off-site wells.

Perched River Seepage

Perched seepage, or bed loss, represents seepage from a creek or river which is above the water table. The seepage rate is independent of the nearby aquifer water levels; that is, the reach is not hydraulically connected to the aquifer. All perched seepage is entered into the model as a line source. The estimated seepage is distributed among the model cells associated with each perched reach. This information is prepared as input to the Fortran component of the recharge tool, which applies the perched seepage in the estimation of net recharge.

Perched river seepage for rivers and creeks other than the Snake River was estimated from a water balance using gage and diversion data. The same data were often used for both diversion (see section on surface water diversions) and seepage calculations. Figure 23 shows the primary perched reaches. Some of the less significant represented perched reaches (for example, the Birch Creek hydropower discharge) were represented in the model but are not shown on Figure 23. Table 6 contains a complete listing of the represented perched reaches. Table A-2 lists the model cells associated with each of the perched reaches.

Data were not always available for every gage for every year. The following section summarizes how the seepage from each perched reach was estimated. For a complete description, the reader is referred to ESPAM Design Document DDW-024.

Camas Creek and Lone Tree. Flood-control diversion volumes (USGS, 2002) were applied as a line source at the Lone Tree spreading location. Camas Creek perched-river seepage (bed loss) was based on the difference in flow between two gaging stations at Camas Creek. The upper gaging station is Camas Creek at Red Road near Kilgore and the lower is Camas Creek near Camas. Corrections were made for diversions at Lone Tree and irrigation diversions between the two gages (Shenton, 2002).

The Red Road gage data series (the north end of the losing reach) was incomplete. Thus, the final perched seepage values used in model calibration were based on gage data for all periods where data were available and estimated seepage where Red Road gage data were not available.

Medicine Lodge Creek. Medicine Lodge Creek lies partially inside and partially outside the model study area. GIS analysis shows that 45% of District 32-c irrigated lands are within the study area. Medicine Lodge Creek sinks into the Snake River Plain south of the irrigated lands. Bed loss was calculated by subtracting the inside-study-area diversions from the gaged flow of Medicine Lodge near Small, Idaho. The gaging station for Medicine Lodge began to function during the summer of 1985; records were not kept prior to that date. For years after 1985, the “Big Lost River Below Mackay Reservoir” gaging station was compared with Medicine Lodge creek gage records using linear regression. This produced a reasonable relationship, which was applied to the years before 1985. For all years before 1985, the predicted Medicine Lodge gage record was

used with actual diversions in calculating bed loss. Actual data were used to calculate bed loss for all years after 1985.

Birch Creek and Birch Creek Hydropower Plant. The bed loss and diversion calculations for Birch Creek are divided into two different time periods. Before 1987, water was delivered to Reno Ranch through a ditch with an estimated 50% bed loss. After 1987, water was diverted into a lined canal and pipeline and delivered to the Birch Creek hydroelectric plant before being used by the Reno Ranch (Sorenson Engineering, 2002).

Prior to 1987, Birch Creek was measured at the USGS gage station "Birch Creek at Eight-mile Canyon Road Near Reno Idaho." Water measured by this gage station was then diverted into the old Reno Ranch ditch during summer months. Excess water (and all water during winter months) was allowed to continue downstream and flow out onto the desert.

For months when the Eight-mile gage station was not active, gage records were predicted using regression based on Birch Creek diversions. Prior to 1987, half of the reported diversions were applied as diversions to irrigation entity IESW037. The Eight-mile gage record, minus diversions applied to IESW037, was applied as perched river seepage (bed loss) in the natural channel of Birch Creek within the study area. This actually applied the 50% ditch loss from the old ditch to the natural channel of Birch Creek, but since the old ditch is outside the model study area, seepage from the ditch actually enters the model domain as sub-surface flow in the model cells near the creek channel.

During the summer of 1987, the Birch Creek hydroelectric plant began to operate and the Eight-mile gage was discontinued. The entire flow of Birch Creek is delivered to the plant through a lined canal and pipe system. Outflow from the plant is applied to irrigation of the Reno Ranch or delivered to a channel where it infiltrates into the subsurface. Discharge records were obtained from the Birch Creek hydroelectric plant for use in calculating bed loss (Sorenson Engineering, 2002), in combination with watermaster diversion records.

Camas National Wildlife Refuge and Mud Lake. For the wildlife refuge, surface-water delivery volumes are recorded by the watermaster. These volumes are applied to a GIS line feature along the axis of the wetland.

Camas Creek inflows to Mud Lake. In some years, particularly during the winter, Camas Creek supplies water to Mud Lake. In the perched river seepage data set, Camas Creek inflows are applied as perched river seepage (recharge to the aquifer) to a GIS line feature that occupies the same model cells as the lake. Summertime values are obtained from watermaster records (Shenton, 2002). Wintertime inflows are not recorded directly, but are computed from a mass-balance calculation of October and May lake contents, winter-time pumping to the lake, and estimates of winter-time ET and precipitation, using watermaster-supplied data.

Mud Lake Flood Control. In high water years, water is pumped from Mud Lake to the desert south of the farm lands as a flood control measure. Data are obtained from watermaster records. No irrigation diversions are associated with this perched river seepage site.

Little Lost River and Little Lost River Flood Control. Because the Little Lost River infiltrates to the aquifer a short distance beyond the irrigated lands, perched river seepage is calculated as the difference between flow at the Little Lost River gage (very near the model boundary) and diversion volume.

When annual diversion volumes were interpolated to monthly values based on percentages from 2001 daily records, many negative bed loss values were generated. To correct this condition, annual diversion volumes were distributed temporally according to summer gaging station temporal patterns. This gave a more reasonable distribution without causing negative bed loss values.

The gaging station at "Little Lost near Howe" was decommissioned in 1991. A number of prediction options were explored to estimate gaging records for the last years of the model calibration period. A linear regression based on precipitation at the Howe gage was the selected method.

Using the predicted yearly gage station record for years after 1991, yearly diversions were subtracted to give a total bed loss for each year. Annual values were interpolated to monthly results using percentages from the pre-1991 data. To smooth the time series, months were grouped together and averaged. The groups were April-Oct, Nov-Feb, and March.

In 1985, a flood-control spreading area was developed up-river of Little Lost River diversions. During winter months water is diverted to the spreading area to prevent icing and local flooding. Another line source was developed to show this location as a point of recharge during winter months. Prior to 1985, wintertime bed loss is applied to

the channel of the Little Lost River below the gage. For 1985 and later years, it is applied to the spreading area. Summertime bed loss is always applied to the river channel.

Big Lost River. The entire irrigated area of the Big Lost Valley that is included within the model area is bounded between two gages on the Big Lost River. The river flows through irrigated lands throughout this area, and there is a fairly dense network of diversion canals and laterals throughout the irrigated area. The gage data were complete for the entire calibration period. Therefore, the recharge associated with surface water irrigation, canal leakage and perched river seepage was all lumped into the surface-water irrigation calculation. For summer months, the entire difference between the upstream gage (Mackay Dam) and the downstream gage (Near Arco) was applied as a diversion to irrigation entity IESW005. In the winter months, the entire difference was applied as bed loss (perched river seepage) to the line feature representing the riverbed, illustrated in Figure 23. This resulted in some wintertime negative values, which could be consistent with the processes of periodically gaining reaches and of lagged return flows. These are both physical possibilities, so the negative values were retained in the data. Three gages below Arco and records of diversions to a flood-control spreading ground at the Idaho National Laboratory were used to spatially distribute any water discharging past the Near Arco gage to the spreading ground and lower reaches of the river.

Big Wood River and Little Wood River. Most of the Big Wood River was represented with no perched seepage because the bed loss calculated from gage data oscillated about zero, with a very small magnitude relative to stream discharge. Upstream and downstream gage data (adjusting for diversions and returns) were used to calculate bed loss in the Little Wood River, the lower reach of the Big Wood River, and

the reach of the Big Wood River identified in Table 6 as the "Below Magic Reservoir" reach, just below the reservoir.

Twin Falls Canal and Lake Murtaugh. Because nearly all of the Twin Falls Canal Company lands lie outside the study area, the diversions applied to irrigation entity IESW041 were discounted substantially. However, the leaky portion of the canal within the study area and a part of Lake Murtaugh within the study area contribute recharge to the aquifer based on total diversions. Because of the large volume of recharge relative to the small fraction of diversions applied to the model, these leaky features were not treated with the leaky canal function of the GIS/Fortran Recharge Tool. Instead, recharge for these locations was calculated in a spreadsheet using the full diversion volume, and applied in recharge calculations as perched river seepage to the location illustrated in Figure 23. Leakage calculations relied upon data from Twin Falls Canal Company (circa 1955).

Table 6 lists the average perched seepage for each reach. Both average stress period seepage and average annual seepage are listed in Table 6.

Steady-State Model Water Budget

During compilation of water level data, it became apparent that there was an 18.5-year period (May 1, 1982 to October 31, 2000) during the 22-year model calibration period where aquifer water levels across the eastern Snake River Plain started and ended at approximately the same levels. This suggests that during that period, there was no net change in aquifer storage or, stated otherwise, that on the average during that period the inflows were equal to the outflows. This period was selected as the steady state period for the ESPAM. To generate the recharge for the steady state model, each component of

recharge was averaged for that period. Figure 44 shows a bar graph of the elements of the steady state recharge. River gains in Figure 44 represent the net of Snake River and Henrys Fork gains and losses above Minidoka and spring discharges in the Milner to King Hill reach. Figure 45 shows a map of the areal distribution of steady state recharge.

Transient Model Water Budget

All of the components of recharge described above were estimated for each of the 44 transient model stress periods and were processed through the GIS/Fortran Recharge Tool. The output of the Fortran component of the recharge tool is the MODFLOW-formatted well file or recharge array which contains the net recharge or discharge for every model cell for every stress period. Figure 46 shows a graph of the annual net recharge for the 22-year period, graphed along with precipitation for the same period. There are several striking features to note in Figure 46. The amount of net aquifer recharge is highly correlated to the amount of precipitation. Precipitation contributes to net aquifer recharge in three ways: precipitation is the basis for the water supply for surface water irrigation, high summer precipitation reduces the requirement for ground-water pumping and precipitation contributes directly to aquifer recharge via recharge on non-irrigated lands. Additionally, in a high precipitation year, carryover water will be left in the reservoirs for use in the following season, helping to sustain the supply of water available for aquifer recharge in the following year. Another striking feature from Figure 46 is that there is a 4.7 million acre-foot variation in estimated annual recharge to the aquifer, ranging from a high in 1984 of approximately 7.5 million AF to a low in 1989 of approximately 2.8 million AF. These dramatic variations in net aquifer recharge will cause dramatic variations in aquifer water levels.

Figures 47 and 48 show the spatial distribution of transient recharge for the irrigation season and the non-irrigation season, respectively, for 1980-1981. Comparison of Figures 47 and 48 shows that irrigated agriculture plays a significant role in net aquifer recharge.

Model Calibration

The ESPAM was calibrated using automated parameter estimation tools. The goal of model calibration was to adjust model parameters (transmissivity, aquifer storage, riverbed conductance and drain conductance and elevation) until model-predicted values of aquifer water levels and discharges to the river matched observed values. The calibration was done in two steps. An initial steady state calibration was done to establish initial aquifer transmissivity and riverbed and drain conductance. After the initial steady state calibration, a coupled steady state and transient calibration was done. During the coupled steady state and transient calibration, the parameter estimation software would adjust aquifer storage and drain elevation during the transient portion, followed by a check of the steady state model fit. This forced the transient calibration to not only provide a ‘best fit’ to the transient data but to also honor the steady state observations. Changes to the transmissivity field and riverbed and drain conductance were allowed during the coupled steady state/transient calibration.

The following sections describe the parameter estimation tools used for ESPAM calibration, the collection of aquifer observation data used during model calibration and the initial steady state and final coupled steady state/transient calibrations. Final model parameters and a comparison between model-predicted values and observed values are presented in the section describing the coupled steady state/transient calibration.

Parameter Estimation Tools

PEST, a nonlinear, least-squares inverse modeling program developed by Doherty (2004) was used to calibrate the model. (PEST is available for download on the web at *www.sspa.com/pest*.) During calibration, PEST runs the MODFLOW model thousands of times, comparing model-predicted results with observations. After each model run, the objective function is analyzed to determine whether the model run was an improvement over the previous run. After each model run, PEST evaluates each adjusted parameter to determine the next best adjustment to that parameter. PEST then prepares the input data set for the next model run with the adjusted parameters, runs the model and re-evaluates the output. The goal is a weighted, least-squares optimization of the fit between the model-predicted values and the observations.

A key to success at using parameter estimation tools is to have a greater number of observations than parameters being estimated. With previous parameter estimation packages (including previous versions of PEST), this was accomplished by establishing zones of transmissivity and aquifer storage. The parameter estimation software would be tasked to calibrate a single parameter value for each zone, thus greatly reducing the number of parameters being estimated for the entire model. The delineation of the zones was subjective and the calibrated model had abrupt changes in parameter values at zone boundaries.

PEST allows an option of using “pilot points” where parameter values are estimated at user-specified points. PEST interpolates model parameter values between the pilot points using kriging or some other spatial interpolation scheme. For example, during ESPAM calibration using PEST, transmissivity was estimated at 169 pilot points. The transmissivity at these 169 points was interpolated to the entire grid of 11,000 active

model cells. Similarly, aquifer storage, which has a much lower degree of variation than transmissivity, was estimated at 28 pilot points and interpolated to the whole grid. Doherty (2003) provides a more rigorous description of pilot points and how the process works. Additionally, PEST was instructed to calibrate riverbed conductance at the five reaches of the upper Snake River and drain conductance and elevation at the six spring reaches in the lower Snake River. At each calibration run, PEST minimized the difference between observed and model-predicted aquifer water levels and river gains.

River Gain/Loss Calibration Targets

For the upper Snake River, the river gain/loss calibration targets were estimated using the IDWR Reach Gain/Loss Program. The Reach Gain/Loss Program uses gaged reach inflows and outflows, measured diversions and estimated irrigation returns and reservoir storage and evaporation to calculate a water balance for the reach. The residual of the water balance is the estimated river reach gain from or loss to the aquifer. More information on the IDWR Reach Gain/Loss Program can be obtained directly from IDWR. Inputs to the Reach Gain/Loss Program include measured diversions, gaged river flows, reservoir stage and irrigation return flow lag factors (described above). For the purposes of the ESPAM modeling, the newly calculated return flow lag factors were entered into the Reach Gain/Loss Program input files.

Figures 49 through 53 show the estimated monthly reach gain for the five reaches of the upper Snake River (Ashton to Rexburg, Heise to Shelley, Shelley to Near Blackfoot, Near Blackfoot to Neeley and Neeley to Minidoka). As can be seen in Figures 49-53, there is a lot of noise in the monthly data. Prior to use as calibration targets, the

monthly reach gains/losses were filtered to eliminate some of the noise (see transient calibration section).

The streamflow gages on the Snake River are maintained by the USGS and are assigned a rating of “excellent,” ”good” or ”fair,” with associated uncertainty bands of ± 5%, ± 10% and ± 15%, respectively. Each of the upstream gages for the five reaches of interest is rated “good.” Given the “good” rating, the uncertainty on the inflows for each reach is approximately ± 10%. In general, assuming that there is no systematic error introduced at a gage, the ± 10% uncertainty is for an instantaneous measurement. Assuming no systematic error, the uncertainty in the river discharge should be reduced as single day measurements are aggregated into weekly or monthly measurements.

The uncertainty in the estimated river gain or loss is driven by a) uncertainty in both the upstream and downstream gages, b) uncertainty in measured diversions, c) uncertainty in estimated irrigation return flows and d) uncertainty in reservoir storage and evaporative losses. The estimated reach gain or loss cannot be more accurate than the least accurate component. In order to provide a sense of the magnitude of the estimated river gain or loss relative to gage uncertainty, Figures 49 through 53 also show an uncertainty band of ± 5% of the upstream gage. This is not a statement of the true uncertainty of the estimated reach gain or loss but is provided as a guideline for the magnitude of the gain or loss relative to a conservative uncertainty band on the gaged inflow.

If the estimated reach gain or loss is approximately the same magnitude as the ± 5% band, then there is low confidence that the reach is gaining or losing. Figure 53 shows that the magnitude of the Neeley to Minidoka estimated reach gain is almost

always within this ± 5% band; hence, there is significant uncertainty that this reach is gaining or losing. In contrast, Figure 52 shows that the magnitude of the Near Blackfoot to Neeley estimated reach gain is significantly greater than the ± 5% band; hence there is more confidence that this reach is gaining. The estimation of river gain and loss calibration targets is further discussed in ESPAM Design Document DDM-017.

Spring Discharge Calibration Targets

Spring discharge calibration targets proved to be something of a challenge for the ESPAM project. Very few of the springs in the Thousand Springs region are measured with any regularity or accuracy. For many of the springs in the region, it is difficult to discern the discharge point of the spring. Many of the springs have complex plumbing which routes the collected water to various users, making measurement difficult.

The USGS estimates the total annual spring discharge from the regional eastern Snake River Plain aquifer (excluding spring discharge from the Twin Falls area on the south side of the river) based on a regression equation developed by Kjelstrom (1995b). The regression equation uses measured flow at several index springs. However, the Kjelstrom method addresses neither seasonal nor spatial variation in spring discharge. Table 21 lists the annual estimated reach gain from the north side in the Milner to King Hill reach for the calibration period.

In order to compensate for this lack of data, the ESPAM modeling team and the ESHM Committee agreed to try to spatially distribute the total reach gains as predicted by the Kjelstrom method according the magnitude of the springs recorded by Covington and Weaver (1990). For each of the spring sub-reaches shown in Figure 21, the relative magnitude of spring discharge in the sub-reach to spring discharge in the whole reach

was estimated. These estimates were based on the Covington and Weaver (1990) estimates. Table 22 lists the relative magnitude of the six spring sub-reaches from Milner to King Hill and the percent of the total reach gain that each represents. Temporal discretization was done using the seasonal variation in measured springs such as Blue Lakes, Crystal and Box Canyon, which were deemed representative of the springs in the whole reach. This was the method initially used to generate spring calibration targets in the Thousand Springs reach. This method was successful for generating average spring reach calibration targets for steady state calibration. During transient model calibration, however, it became apparent that springs varied markedly in their temporal discharge patterns. Thus the initial method of generating spring targets was unsuccessful for use in the transient calibration.

The second approach, which ultimately was successful for transient calibration, was to use actual spring measurements for the springs for which measurements exist. Initially, the springs for which long-term measurements existed were: Devils Washbowl, Devils Corral, Blue Lakes, Crystal Springs, Clear Lakes, Briggs Springs and Box Canyon Springs. The two springs with the greatest magnitude of discharge, Thousand Springs Power Plant and Malad Gorge Power Plant, did not have discharge measurement records.

At the request of the modeling team, Idaho Power used power generation records at the two plants to estimate spring discharge for Malad and Thousand Springs. Although not obtained through direct measurement, these turned out to be reasonable proxies for measurements of the springs at Malad and Thousand Springs. Once those hydrographs were obtained, transient model calibration was successful. Figure 54 shows the location of the individual springs used as calibration targets. Hydrographs of the measured (and

estimated) springs will be presented in figures in the discussion of transient model calibration. Table 23 lists the model cells representing the springs used as transient calibration targets. Table 24 lists the number of observations and the date range of the observations for each of the calibration target springs. In addition to using monthly spring measurements, the mean discharge and standard deviation of each spring were also used as calibration targets. The annual Kjelstrom estimate of total spring discharge for the entire Milner to King Hill reach as well as the estimated sub-reaches were used to help evaluate the model fit. The estimation of spring discharge calibration targets is further discussed in ESPAM Design Documents DDM-018 and DDM-008.

Aquifer Water Level Calibration Targets

Aquifer water level calibration targets were obtained from the IDWR data base of Idaho aquifer water level measurements using the program WellLog. The WellLog data base includes measurements from the USGS, IDWR, Idaho Power and private consulting firms contracted by the agencies to conduct water level measurements. More information about WellLog can be obtained in the WellLog user's manual (IDWR, 1997c).

Several synoptic measurements (mass measurements) of aquifer water levels were done in 1980-1981 as part of the USGS Regional Aquifer-Systems Analysis effort on the eastern Snake River Plain. This entails measuring as many wells as possible throughout the study area in a short period of time in order to estimate a regional potentiometric surface. As part of the current study, three additional synoptic measurements were done; in Spring, 2001, Fall, 2001 and Spring, 2002. This provided mass measurements at the beginning and ending of the model calibration period.

WellLog was queried for all depth to water measurements within the study area within the calibration period. Depth to water measurements which were documented to be in aquifers other than the regional aquifer, such as locally perched zones, were excluded. Similarly, depth to water measurements which appeared flawed (perhaps an error in recording or a measurement taken shortly after a well was pumped) were discarded. If neighboring water level measurements corroborated a seemingly spurious measurement, the measurement was retained.

Wellhead elevations were estimated using USGS 10 meter digital elevation maps (DEMs) intersected with the IDTM position of each well. This was done using GIS software. An analysis of the accuracy of this technique was done by comparing the elevation determined using 10 meter DEMs versus surveyed elevations where they existed. It was found that, on the average, the elevation determined from the DEMs was within 1.21 ft of the surveyed elevation. This was considered acceptable accuracy by the ESHM Committee. More detail on the use of DEMs for estimating wellhead elevation can be found in ESPAM Design Document DDM-011.

Using the estimated wellhead elevations and the measured depth to water, water table elevations were calculated for each measurement. Figure 10 illustrates water table contours from the Fall 2001 mass measurement. More detail on the collection of aquifer water level data can be found in ESPAM Design Document DDW-014.

Initial Steady State Calibration

Steady-State Calibration Data

Although true steady state conditions rarely exist in natural aquifers, most ground water modeling efforts include a steady state analysis because the transmissivity

distribution tends to be more sensitive to steady state water levels than transient water levels. As previously stated, the net change in aquifer storage, as indicated by water levels between May 1, 1982 and October 31, 2000 was small, so the period was selected as the steady state period. At steady state, the recharge and discharge for an aquifer system are balanced and no water is entering or leaving aquifer storage.

Steady state calibration water level targets were generated by averaging water level measurements for this period. Wells with only one observation during this time period were not used as targets. A total of 1009 steady state aquifer water level observations were used. Figure 55 shows the locations of the wells used as observations for steady state calibration. Figure 55 also shows the location of the river and spring reaches. The reader will note in Figure 55 that many of the wells used for steady state calibration targets are located reasonably close to the river and spring reaches. This helps to control the certainty of the calibrated parameters in these areas of high interest. In areas with few observation wells, the calibration parameters are less certain.

Steady state river gain targets were estimated by averaging the transient river gains for each of the five sub-reaches for the steady state period. Similarly, steady state spring calibration targets were estimated by averaging the transient spring reach targets for the steady state period. Table 25 lists the steady state river and spring calibration targets.

Steady-State Calibration Procedure

During steady state calibration, the model parameters of aquifer transmissivity and riverbed and drain conductance were estimated. The steady state calibration was accomplished using 1020 observations and 180 adjustable parameters. The observations

include 1009 aquifer water level observations, five river reach gain/loss observations, and six spring reach observations. The adjustable parameters include 169 pilot points used to adjust the transmissivity distribution, five river parameters to adjust riverbed conductance for the five river reaches, and six drain parameters to adjust drain conductance for the six spring reaches. Figure 56 shows the location of the pilot points used for calibration of aquifer transmissivity.

The steady state calibration was accomplished by minimizing the difference between model-predicted steady state aquifer water levels and Snake River gains and losses and the averaged observed water levels and averaged estimated Snake River gains and losses and spring discharges. The steady state calibration was done using PEST parameter estimation tools. During the steady state calibration, model-predicted aquifer water levels, which are generated for the center of each model cell, were interpolated to the actual location of each observation well prior to comparison.

The same steady state calibration targets and calibration procedure were used during the initial steady state calibration and during the coupled steady state/transient calibration. The product of the initial steady state calibration is an intermediate product. The ending steady state heads and aquifer transmissivity and riverbed conductance became the starting values for the coupled steady state/transient calibration. The coupled steady state/transient calibration yielded both calibrated steady state and transient versions of the ESPAM.

Coupled Steady State/Transient Calibration

Transient Calibration Data

The transient calibration data include aquifer water level observations, monthly Snake River gains and losses, and spring discharge observations. Transient calibrations are undertaken primarily to determine specific yield. Changes in aquifer water level are a function of aquifer storage or specific yield; hence transient model water level targets are changes in water levels, not the absolute measured water levels. Modeled aquifer water levels were also converted to changes in water levels for comparison with the targets. For the ESPAM calibration, three different types of transient aquifer water level data were used as calibration targets: 1) seasonal wells - wells with long time series consisting of frequent observations (9548 total observations in 39 wells over a maximum of 17 years), 2) mass measurement wells - water level observations collected between spring 2001 and spring 2002 as part of this project (1766 total observations in 601 wells), and 3) trend wells - wells with regular spring-time observations (1403 observations in 173 wells). Figure 57 shows the locations of the transient aquifer water level observation wells.

As during the steady state calibration, model-predicted aquifer water levels are interpolated from the center of the model cell to the actual location of the observation wells. For the transient part of the calibration, a similar interpolation was also done in time. The model-predicted water levels are generated at every model time step (in the case of the ESPAM calibration, every 18.2 or 18.3 days). During calibration, the PEST software interpolated model-predicted water levels to times which match the actual dates of aquifer water level observations.

The monthly gains and losses for the five river reaches above Milner Dam which were computed using the IDWR Reach Gain/Loss Program proved to contain significant measurement noise, so the data were filtered in a computer program called TSPROC (Doherty and Johnston, 2003) prior to their use as calibration targets. TSPROC uses a 1-stage, low passButterworth filter to remove excessive noise in time series data sets. For the ESPAM application, the cutoff frequency was 5.48e-4. Model-predicted river gains were filtered using TSPROC and matched with the filtered observations.

Measured discharge data from Devils Washbowl, Devils Coral, Blue Lakes, Crystal Springs, Clear Lakes, Briggs Springs and Box Canyon Springs were used as calibration targets, as were the spring discharge estimates for Thousand Springs and Malad which were estimated from power records. In general, these spring discharge data were not as noisy as the river gain and loss estimates from upstream reaches and therefore were not filtered. Model-predicted spring discharge at the model cells noted in Table 23 were interpolated in time and then compared with the measured spring discharges. Despite the fact that these individual springs were explicitly modeled, the ESPAM is a regional model and is not intended for predictions of impacts to individual springs. A regional model is limited to replicating broad-scale heterogeneity in the physical system and cannot replicate localized heterogeneities.

Coupled Steady State/Transient Calibration Procedure

The coupled steady state/transient calibration was done using PEST parameter estimation software. During the transient part of the calibration, aquifer specific yield was calibrated at 28 pilot points (see Figure 56), spring (drain) elevation was estimated at the model cells representing the springs used as calibration targets and spring (drain)

conductance was estimated at the six spring reaches and the nine drains used as calibration targets. The steady state portion of the calibration was as described above. The ending heads from steady state were used as starting heads for the transient calibration. During the coupled steady state/transient component of each calibration model run, PEST was allowed to modify aquifer transmissivity and river and drain conductance as well as establish aquifer specific yield and spring elevations. After each pair of steady state and transient model runs, the model-predicted aquifer water levels and river and spring discharges were compared with the thousands of calibration target values. The coupling of the steady state and transient models during transient model calibration forced the calibrated transient model to match both the steady state and transient calibration targets, ensuring that there was minimal degradation in the match to the steady state data caused by the transient calibration.

The objective of the transient part of the model calibration was to minimize the difference between observed river gains and losses, spring discharges and water level changes between May 1, 1985 and April 30, 2002. The transient model required a warm-up period of about five years because observations during the initial 1980-1985 period are partly dependent on events that occurred years prior to 1980. By using the ending steady state heads as the transient starting heads, the impacts of recharge and discharge in the years prior to 1980 were approximated. When the model was allowed to run with estimated recharge and discharge data from 1980 to 1984, by 1985 the model was responding appropriately based on comparison with measured values (river gains and losses and aquifer water levels).

The coupled steady state/transient calibration utilizes about 16,600 observations and 225 adjustable parameters. The observations include 12,700 aquifer water level change observations, 1300 Snake River gain/loss observations, 1500 spring discharge observations and the previously mentioned steady state observations. The adjustable parameters include 169 pilot points to adjust the transmissivity distribution, 28 pilot points to adjust the specific yield distribution, 5 river parameters to adjust riverbed conductance for the five river reaches, and 9 drain conductance parameters and 9 drain elevation parameters at model cells with spring records.

When data entry errors in the calibration targets were discovered in ESPAM Version 1.0, the coupled steady state/transient calibration was re-run using the corrected reach aggregations and upper Snake River calibration targets. Keeping all initial estimates of calibration parameters and the overall calibration methodology the same as were used for Version 1.0, making only the changes required for correcting the data entry errors in the previous calibration, the PEST calibration was re-run to generate ESPAM Version 1.1. The statistics and parameters discussed below are for ESPAM Version 1.1. These data entry errors, however, did not significantly affect results of the model simulation.

Steady State Calibration Model Fit

Model residuals (the difference between model-predicted and observed values) are generated by the PEST software, providing an indication of how well the model-predicted values match the observed values. Model statistics for the steady state calibration indicate an overall R^2 between measured and modeled aquifer water level observations of 0.9943. The standard error for the aquifer water level estimates is 17.84

ft indicating that about 95 percent of the modeled aquifer water levels are within about 35.6 ft of observed values, which represents less than 2% of the head change in the aquifer between St. Anthony and King Hill, Idaho. Figure 58 shows a scatter plot of model-predicted versus observed aquifer water levels. Figure 58 shows an excellent match between the predicted and observed aquifer water levels. A regression line for the data indicates a slope of .9936 and an intercept of 28.618. With a perfect match, each point in Figure 58 would fall on a line with a slope of 1 and an intercept of 0. Relative to the range of values on either axis, 28.618 is very nearly zero. Figure 59 shows a map with water level contours for both the model-predicted and observed aquifer potentiometric surface. Figure 59 also shows an excellent fit between the model and the steady state observations.

Steady state model-predicted versus observed discharge to river and springs is shown in a scatter plot in Figure 60. Figure 60 shows an excellent fit between model-predicted and observed discharges to the river, with an R^2 value of .9878. The regression line which fits the data in Figure 60 has a slope of 1.0107 and a y-intercept of 679,326. Table 25 lists the model-predicted and observed steady state river and spring discharges.

Transient Calibration Model Fit

Comparison of Simulated and Observed Transient Heads

One of the measures of a transient calibration is how well the model simulates measured aquifer water levels over time. Figures 61 through 65 show transient model-predicted versus observed water levels. On Figures 61 through 65, the transient comparisons are sited on maps of the study area with pointers to the location of each hydrograph. In each of these figures, the pink line represents the model-predicted values.

Wells with multiple measurements each year for a long period were selected to calibrate the ESPAM's model ability to replicate the seasonal changes in aquifer water level. Figures 61 and 62 show eight selected wells with seasonal fits. The ability of the model to replicate seasonal aquifer water level changes is a function of aquifer storage and transmissivity as well as the model recharge and discharge. Figures 61 and 62 show that the ESPAM does a very good job of matching seasonal aquifer water level data. The standard error for the seasonal aquifer water level ovservations is 1.84 ft.

Wells with a spring observation for each of many years were selected to test the ESPAM's ability to replicate the long-term trend of aquifer water levels for the calibration period. Figures 63 and 64 show model-predicted versus observed aquifer water level trend data. Similar to the seasonal data, a model's ability to match trend data is a function of aquifer storage, transmissivity and model recharge and discharge. Figures 63 and 64 show that the fit to trend data was very good. The standard error for the trend data is 5.83 ft.

Figure 65 shows the model's fit to the mass measurement data which was collected for three periods at the end of the calibration period. Figure 65 also shows a reasonable fit to the mass measurement data. The standard error for the mass measurement data is 5.17 ft.

Comparison of Simulated and Observed River Reach Gains

Figures 66 through 70 show the filtered modeled gains in the upper Snake River versus the filtered observed gains. Figures 71 through 75 show the same data, without the filtering. Figures 66 through 70 and 71 through 75 represent reach gains in the Ashton to Rexburg, Heise to Shelley, Shelley to Near Blackfoot, Near Blackfoot to

Neeley and Neeley to Minidoka reaches, respectively. The pink line in Figures 66 through 70 represents the model-predicted values. The observation data shown in Figures 66 through 70 is the filtered data shown in Figures 49 through 53, as previously discussed. In each river reach, no attempt was made to match the first five years of data due to the transient model warm-up period. As can be seen in Figures 66 through 70, the model does a reasonable job of predicting reach gains in each reach of the upper Snake River. For the Neeley to Minidoka reach, the measured data shows that the reach gain is somewhat erratic, year to year, but is a slight gain on the average. The model predicts an almost constant modest gain for Neeley to Minidoka. Inspection of Figure 53, the raw monthly reach gain observation data versus gage uncertainty for the Neeley to Minidoka reach, shows that this reach effectively, on the average, has a slight gain. Hence, the model-predicted value was considered reasonable.

Figures 71 through 75, the comparison of unfiltered model-predicted versus measured river gains, show the seasonal variation of both the measured and predicted river gains. The model generally under-predicts the month to month variation of the measured data; however, inspection of the unfiltered measured reach gains shows a significant amount of noise in the data, reflecting uncertainty in instantaneous river gage measurements.

Comparison of Simulated and Observed Spring Discharges

Figures 76 through 84 show the model-predicted versus observed spring discharges for the following springs: Devils Washbowl, Devils Corral, Blue Lakes, Crystal, Clear Lakes, Briggs, Box Canyon, Thousand Springs and Malad. As with previous transient hydrographs, the pink line represents the model-predicted values in

Figures 76 through 84. As can be seen in Figures 76 through 84, the model does an excellent job of predicting the magnitude of the spring discharge for each spring. The model underestimates the seasonal amplitude of spring discharge for Crystal, Briggs, Box Canyon, Thousand Springs and Malad. The measured seasonal amplitude for these springs is approximately 20% and the model-predicted seasonal amplitude is approximately 9%.

Calibrated Model Parameters

Aquifer Transmissivity

Simulation results indicate a wide range in transmissivity from about 125 to 4.9 x 10^7 ft^2/day (Figure 85). Riverbed and drain conductance ranges from 10.3 to 1.57x 10^7 ft/day/ft. Final values for riverbed and drain conductance can be found in Tables 3 and 4, respectively. Figure 86 shows the ratio of the final ESPAM transmissivity to the preliminary steady state transmissivity. As can be seen in Figure 86, the preliminary steady state transmissivities were scaled by as much as an order of magnitude during the coupled steady state/transient calibration. This represents the amount of change required in the initial steady state transmissivity field in order to accommodate the transient data.

The map of the calibrated model transmissivity (Figure 85) shows that estimated transmissivity values tend to be lower along the margins of the plain and higher towards the center. Two major exceptions to this generalization include the Mud Lake barrier and the Great Rift. The Mud Lake barrier extends east to west across the aquifer from the Bitterroot Mountains to just south of the confluence of the Henrys Fork and the South Fork of the Snake River. The Great Rift extends north to south across the plain from the Big Lost River Valley to just west of American Falls Reservoir. The transmissivity of

both of these features is lower and impedes ground water flow as evidenced by the more tightly spaced equipotential lines in these areas. These features in the calibrated transmissivity distribution match our current understanding of the aquifer.

Aquifer Storage

The transient component of a model calibration is primarily used to calibrate aquifer storage (storativity or specific yield). In the case of the ESPAM, the confined representation of the physically unconfined system uses aquifer storativity (rather than the unconfined parameter of specific yield). However, unlike a truly confined system, the storativity values expected for the ESPAM would be in the range of .001 to .3, a range much more typical of specific yield. For a truly confined aquifer, storativity values would be several orders of magnitude smaller.

During the coupled steady state/transient calibration, aquifer storage was calibrated at 28 pilot points (Figure 56) and interpolated to every model cell. Aquifer storage has a much lower degree of spatial variation, so fewer pilot points are required for calibration. The aquifer storage distribution ranges from 5.2×10^{-3} to 0.280 (Figure 87).

Drain Elevation

After the coupled steady state/transient calibration, drain elevations, which were modified as part of the calibration, were assessed relative to the ending steady state heads. It was noted that some of the ending drain elevations were within a few feet of the ending steady state heads. The ESHMC discussed the fact that the ending drain elevations were high relative to the ending steady state aquifer levels, with the potential result that drains would shut off with minor declines in aquifer water level. It was agreed that the true elevations of the drains are unknown but that an absolute discontinuation of

major portions of spring discharge due to a minor change in aquifer water level would be unreasonable.

As previously noted, Equation 7 is the governing equation for aquifer discharge through a drain. Inspection of Equation 7 shows that discharge is directly proportional to the conductance of the drain as well as to the elevation differential between the aquifer level and the drain elevation. The ESHMC discussed the fact that drain elevations could be changed with a corresponding change in drain conductance to alleviate this concern without changing the calibration or any major functionality of the model. To achieve this modification, all drain elevations were checked against the ending aquifer water levels in the same model cell. Any drain elevation which was within 30 feet of the ending steady state aquifer water level was adjusted to an elevation 30 feet lower than the ending state aquifer water level at the drain location. A corresponding adjustment was made to the drain conductance in that model cell to keep the drain discharge the same. Table 4 lists the final values for drain conductance and drain elevation for each model cell representing a drain.

This modification was deemed a reasonable representation of the physical system of springs. In the ESPAM, all model cells, including drain cells, are 1-mile square. A model cell representing a drain should not be considered to represent an individual spring but rather the collective spring discharge along a 1-mile segment of the canyon wall. In the physical system, springs at high elevations will shut off with significant water level declines. This will still be represented in the model as a decline in the spring discharge represented in a model cell. However, it was deemed that the total discharge of a 1-mile segment was more likely to be reduced than to be eliminated by a realistic change in

aquifer water level. Clearly, really significant changes (30 ft or more) in aquifer water levels from the steady state ending heads would result in the wholesale discontinuation of spring discharge in a model cell.

Model Limitations

As with any model of a natural system, the ESPAM has a degree of limitation and uncertainty. Simplifying assumptions must be made to model complex, natural systems. Components of the aquifer water budget which have the least certainty are irrigation return flows, recharge on non-irrigated lands and tributary underflow. As discussed in the Water Budget section, these elements were estimated based on the collective professional judgement of the modeling team and the ESHMC using existing published material. As previously discussed, there is a shortage of data on spring discharges and irrigation return flows. The ESPAM calibration would have been enhanced by the existence of additional measured or estimated spring discharge data and irrigation return flow measurements.

The ESPAM is a regional ground-water model. For this reason, the model is best used for broad-scale predictions. As previously noted, the user should avoid the temptation to model localized impacts, such as impacts to a specific spring.

A primary objective of the model development and calibration was the characterization of the interaction between the aquifer and the river. Although thousands of aquifer water level observations were used during the model calibration the model was optimized for prediction of impacts to the river due to water use on the plain. The model can be used to provide a general sense of ground-water to ground-water impacts,

however, the model is best used for prediction of impacts to surface water resources at a regional scale due to ground-water use.

Despite these noted limitations, the ESPAM is the most thoroughly calibrated model in existence of the eastern Snake River Plain Aquifer. The extensive use of model calibration tools and the prevalence of available data yielded an excellent model calibration.

Related Reports

During ESPAM design and development, a total of thirty-five design documents were written to document important model and water budget decisions. Each design document chronicled the design alternatives, the final design and the rationale for selecting the final design. The design documents were distributed in draft form to the ESHMC for review and feedback. Many of the design documents went through multiple iterations as a result of feedback from ESHMC members either during or after design reviews. Throughout the ESPAM project, draft and final design documents were made available to the ESHMC via the IWRRI web site. If, in the course of final model development or calibration, the documented final design had to be changed, an 'as-built' version of the pertinent design document was released to document the change. Table 26 lists the ESPAM design documents and their status as of this writing.

Summary and Conclusions

This report documents the successful reformulation and calibration of the numerical ground-water model used for water management on the eastern Snake River Plain. The ESPAM was calibrated to 22 years of recharge and discharge data, as compared with the previous SRPAM model, which was calibrated to only one year of

data. Calibration to a long span of years which include some of the driest and wettest years on record ensures that the model is capable of accurately simulating the response of the river/aquifer system to a broader spectrum of stresses.

The ESPAM was calibrated using the PEST suite of parameter estimation tools. Using PEST enabled the modeling team to optimize the fit of the model to thousands of observed aquifer water levels and streamflow measurements. The final calibrated ESPAM shows a significantly better fit to observed data than the previous SRPAM model.

A significant aspect of the ESPAM reformulation and calibration was the involvement of the ESHMC. The ESHMC, comprised of interested parties representing agencies, private industry and water user groups, oversaw the ESPAM reformulation and calibration process. Although the collaborative process used to develop the ESPAM took more time than the more streamlined, conventional model development process, it allowed ESHMC members an active voice in model design and implementation decisions and helped to eliminate bias. By including a broad spectrum of interested parties in the model reformulation and calibration, the committee members were able to gain a better understanding of model design details. The ultimate goal of the process was to allow discussions about future aquifer management decisions to center on policy interpretation and not on the scientific tools used in support of those decisions.

The outcome of any ground-water modeling effort is enhanced insight into the hydrologic processes being modeled. This was also true for the ESPAM reformulation and calibration. Development of the ESPAM underscored several significant gaps in

either data or our understanding of the underlying hydrologic processes. Recommendations for further work include:

a) Long-term collection of spring discharge data in the Thousand Springs area and in the Near Blackfoot to Neeley reach
b) Long-term collection of irrigation return flow data and development of numerical relationships between the collected data and measured surface irrigation diversion data
c) Continued refinement of estimates of evapotranspiration
d) Improved estimates of river gains and losses, including the use of new technology such as acoustic Doppler-based stream gaging instruments
e) Further research on the interaction between the river and the aquifer, particularly in the Thousand Springs and American Falls areas
f) Improved estimates of the contribution to the aquifer from tributary basins

Although every model represents a simplification of complex processes, with the ESPAM being no exception, the ESPAM is the best available tool for understanding the interaction between ground water and surface water on the eastern Snake River Plain. The science underlying the reformulation and calibration of the ESPAM reflects the best knowledge of the aquifer system available at this time. The ESPAM was calibrated to approximately 11,000 observed aquifer water levels and river gain and loss estimates. Calibration parameters indicate an excellent fit to the observed data, providing confidence that the ESPAM provides an excellent representation of the complex hydrologic system of the eastern Snake River Plain.

Complex water management decisions on the eastern Snake River Plain will be greatly enhanced by use of the ESPAM. The participation of the ESHMC members in the model design and calibration process provided members with unprecedented insight into the details of this complex numerical ground-water model, allowing committee members to make informed judgements regarding how the model is applied to aquifer management.

1993	5090
1994	5320
1995	5120
1996	5040
1997	5430
1998	5870
1999	5660
2000	5830
2001	5870
2002	5440

Table 22. Estimated spring discharge by sub-reach in the Milner to King Hill reach.

Subreach Name	Number of Model Cells	Total Discharge (cfs)	Subreach Proportion of Milner to King Hill Discharge
Devil's Washbowl to Buhl Gage	17	1075	0.17
Buhl Gage to Thousand Springs	12	1700	0.28
Thousand Springs	4	1879	0.31
Billingsley Creek	10	204	0.03
Malad Gorge	2	1199	0.19
Malad Gorge to Bancroft Springs	10	97	0.02

Table 23. Model cells representing individually measured or estimated springs.

Spring	Row	Column
Devils Washbowl	66	28
Devils Corral	65	28
Blue Lakes	62	24
Crystal	54	18
Clear Lakes	50	12
	50	13
Briggs	49	11
Box	47	12
	47	13
Thousand Springs	44	12
Malad	36	15
	36	16

Table 24. Summary of spring discharge calibration target data.

Spring Name	Number of Observations	Start Date	End Date
Devils Washbowl	5657	4/6/85	9/30/00
Devils Corral	35	11/6/80	3/6/01
Blue Lakes	7470	5/1/80	9/15/02
Crystal	1802	6/3/85	2/18/02
Clear Lakes	56	10/13/82	1/16/02
Briggs	3462	5/19/80	9/30/98
Box	7458	5/1/80	9/30/00
Malad	217	12/1/84	12/1/02
Thousand Springs	236	5/1/80	12/1/02

Table 25. Steady state river gain and spring calibration targets and model predictions.

Spring or Reach Name	Steady State Target Discharge (ft^3/d)	Steady State Discharge (ft^3/d)
Ashton to Rexburg	2.72E+07	2.67E+07
Heise to Shelley	-5.14E+07	-5.19E+07
Shelley to Near Blackfoot	-6.43E+07	-6.35E+07
Near Blackfoot to Neeley	2.27E+08	2.28E+08
Neeley to Minidoka	7.08E+06	6.97E+06
Devils Washbowl to Buhl	8.66E+07	6.24E+07
Buhl to Thousand Springs	1.37E+08	1.32E+08
Thousand Ssprings	1.51E+08	1.70E+08
Thousand Springs to Malad	6.63E+06	5.34E+06
Malad	9.65E+07	1.04E+08
Malad to Bancroft	7.84E+06	1.14E+07

Table 26. Eastern Snake Plain Aquifer Model Enhancement Design Document Topics

Revised May, 2006

Model Design and Calibration Topic	Author	ESPAM Project Document Number	IWRRI Document Number	Status
Model Design Objectives	Paul Castelin, Donna Cosgrove	DDM-001		Final
Model Boundary	Allan Wylie	DDM-002	IWRRI04-016	Final
Model Layers	Allan Wylie	DDM-003	IWRRI04-019	Final
Model River Representation	Allan Wylie	DDM-010	IWRRI04-017	Final
Estimating Elevation of Wellheads and River Surface	Allan Wylie	DDM-011	IWRRI04-021	Final
Delineating the Bottom of the Aquifer	Allan Wylie	DDM-012	IWRRI04-015	Final
Steady State Response Functions	Donna Cosgrove, Gary Johnson	DDM-013		In Preparation
Transient Response Functions	Donna Cosgrove, Gary Johnson	DDM-014		In Preparation
Model Grid and Grid Orientation	Allan Wylie	DDM-015	IWRRI04-018	Final
Confined vs. Unconfined Aquifer Representation	Allan Wylie	DDM-016	IWRRI04-020	Final

Estimating Reach Gains in the Ashton/Heise to Milner Reach	Brenda Gilliland	DDM-017	IWRRI04-011	Final
Estimating Reach Gains in the Milner to King Hill Reach	Gary Johnson	DDM-018		In Revision
ESPAM Final Report	Donna Cosgrove	DDM-019	IWRRI06-002	Final

Recharge Calculation Topic	Author	ESPAM Project Document Number	IWRRI Document Number	Status
Determination of Crop Mix	Bryce Contor	DDW-001	IWRRI04-025	Final
Percolation, Runoff and Deficit Irrigation	Bryce Contor	DDW-002	IWRRI04-004	Final
Recharge from Precipitation on Non-Irrigated Lands	Bryce Contor	DDW-003	IWRRI04-006	Final
Tributary Underflow	Allan Wylie	DDW-004	IWRRI06-004	Final
Calculating Return Flow Lag Factors	Dick Lutz	DDW-005	N/A	Final
Aggregating Surface Water Canal Companies into Surface Water Irrigation Entities	Brenda Gilliland	DDW-008	IWRRI04-014	Final
Ground Water Irrigation Entities for Recharge Calculation	Bryce Contor	DDW-009	IWRRI04-026	Final
Traditional Evapotranspiration Calculation	Bryce Contor	DDW-010	IWRRI04-009	Final
PRISM Precipitation Maps	Brenda Gilliland	DDW-011	IWRRI04-013	Final
Estimating Irrigation Entity Diversions—Snake	Brenda Gilliland	DDW-012	IWRRI04-012	Final
Historical Gaging Station Locations	Brenda Gilliland	DDW-013	IWRRI04-022	Final

Historical Water Level Measurements	Suzy Shaub	DDW-014	Not assigned	Final
Land Use	Bryce Contor	DDW-015	IWRRI04-007	Final
Estimating ET Using SEBAL	Rick Allen	DDW-016		
Determining Source of Irrigation Water	Bryce Contor	DDW-017	IWRRI04-010	Final
Irrigation Conveyance Losses	Bryce Contor	DDW-020	IWRRI04-008	Final
ET Adjustment Factors	Bryce Contor	DDW-021	IWRRI06-005	Final
Discerning Method of Irrigation Water Application	Bryce Contor	DDW-022	IWRRI04-005	As-Built Version
Non-Snake Perched River Reach Seepage Estimates and Irrigation Diversions	Nathan Erickson	DDW-024	IWRRI06-003	Final
Fixed Point Pumping	Bryce Contor	DDW-026	IWRRI04-027	Final

Recharge Program Topic	Author	ESPAM Project Document Number	IWRRI Document Number	Status
GIS-Based Recharge Program Component Design	Jim Oakleaf	DDR-001	N/A	Final (incorporated in Recharge Tool as help files)
Preparing GIS Recharge Component Inputs	Bryce Contor	DDR-002	N/A	Available as May, 2004 training notes
Fortran-Based Recharge Program Component User's Guide	Donna Cosgrove	DDR-003		In preparation

Field Work Topic	Author	ESPAM Project Document Number	IWRRI Document Number	Status
ADCP Reach Gain Measurement Report—Spring/Fall, 2001	Idaho Power/USGS	DDF-001	N/A	Final
ADCP Reach Gain Measurement Final Report	Idaho Power/USGS	DDF-005	N/A	Final
Return Flow Measurement Plan	Idaho Power	DDF-006	N/A	Final
Return Flow Measurement Data Report—Year 1	Idaho Power	DDF-007	N/A	Final
Return Flow Measurement Data Report—Year 2	Idaho Power	DDF-008	N/A	Final

Scenario Topic	Author	ESPAM Project Document Number	IWRRI Document Number	Status
Base Case Scenario	IWRRI	DDS-001	IWRRI04-001	Final
Curtailment Scenario	IWRRI	DDS-004	IWRRI04-023	Final
No Changes in Surface Water Practices Scenario	IWRRI	DDS-003	IWRRI04-003	Final
Managed Recharge Scenario	IWRRI	DDS-002	IWRRI04-002	Final
Drought Scenario	IWRRI	DDS-005	IWRRI04-024	In preparation
Strawman Scenario	IWRRI	DDS-006	IWRRI05-003	In preparation
A&B Irrigation District Scenario	IWRRI	DDS-007

Appendix B—Description of the GIS/Fortran Recharge Tool

As part of the ESPAM upgrade, the Idaho Water Resources Research Institute at University of Idaho developed a tool for calculating recharge and discharge for MODFLOW ground water models using spatial data. The GIS/Fortran Recharge Tool uses a combination of geographical information system (GIS) technology and a Fortran program to process spatial data to calculate recharge and discharge to each model cell for a ground water model.

The GIS Recharge Tool is independent of model grid or aquifer basin. The tool was designed for use in basins with arid irrigation; however, the tool can easily be adapted to basins with no irrigation. Spatial data inputs to the tool include the model grid, precipitation, evapotranspiration, recharge on non-irrigated lands, land use, soil type and irrigation. Additionally, line source and point source data such as canal seepage, river seepage, tributary underflow and municipal pumping are entered as spatial data. The GIS component of the tool intersects each component of data with the model grid and generates ASCII output files which are input to the Fortran program. Figure B-1 shows schematically how the GIS component of the tool functions.

The Fortran program uses the cell-by-cell information to calculate net aquifer recharge/discharge for each model cell for each stress period and generates the MODFLOW input files. Figure B-2 shows conceptually the individual components of aquifer recharge and discharge which are accounted for by the GIS Recharge Tool.

The tool was developed primarily for use with the Enhanced Snake Plain Aquifer Model but was designed to be applied in other basins as well. The tool design divides functionality between spatial data analysis (the GIS component) and background

computer processing (the Fortran component). This split of functionality allows the analyst maximum flexibility in the processing of the aquifer recharge/discharge. By segregating the background computer processing into a separate Fortran program, the GIS/Fortran Recharge Tool can be used with a parameter estimation package such as PEST enabling dual calibration of aquifer model parameters (transmissivity and storativity) with model recharge.

GIS Component

The GIS component of the recharge tool allows creation of a new simulation and scenario or creation of a simulation based on an existing simulation. Figure B-3 shows the user interface for the GIS component of the tool. As the user builds a recharge data set, the GIS component provides the user with pull-down menus for selection of desired data files or data fields within a file. Figure B-4 shows the user interface for the GIS component of the tool.

The GIS component of the recharge tool allows creation of a new simulation and scenario or creation of a simulation based on an existing simulation. As the user begins building a recharge data set, the GIS component provides the user with pull-down menus for selection of desired data components. Figure B-3 shows the user interface for the GIS component of the tool. Figure B-4 shows the selection of recharge components which the user can choose to analyze. After selecting the recharge component to be analyzed, the user is guided through selecting data files and fields within each file to be used for the analysis. Figure B-5 shows a sample navigation window for locating a data file.

Figure B-6 shows a sample of the data components from the selected file available for analysis. After identifying the data sources, the user selects the

RunAnalysis button and the GIS component processes the selected data, generating the input files for the Fortran component.

The GIS component is designed in a modular fashion, so that part of a recharge data set can be built or modified independently of the rest of the data set. The user can build part of a data set, close the tool, and resume processing of the same data set at a later time. The tool also allows easy modification of an existing data set, for scenario generation. The tool was built for maximum flexibility in generation of model recharge/discharge data.

Fortran Component

The Fortran component calculates recharge and discharge for each individual ground water model cell for each stress period, based on the input data from the GIS component. The Fortran component reads all of the data files created by the GIS component which contain recharge and discharge information for each model grid cell. Outputs of the Fortran component include the MODFLOW Well File or Recharge File, in either binary or ASCII format, (for direct input to the ground water model) as well as output of intermediate recharge variables such as evapotranspiration, precipitation, or applied irrigation water for each model cell for each stress period, which can be viewed using GIS software. This allows the analyst to graph the components of recharge spatially or to graph totals through time, enabling full analysis of the recharge data for error-checking as well as for hydrological analysis.

The Fortran component can be run solely to calculate recharge and discharge values for a single model scenario, or it can be run in conjunction with parameter estimation sofware such as PEST. Figure B-7 shows a flow diagram of how the

GIS/Fortran Recharge Tool would be used for generation of recharge/discharge for a single model scenario.

The recharge tool has also been designed to be run along with the model during parameter estimation. Figure B-8 shows how the Fortran component would be included in a parameter estimation loop using PEST. Inclusion in a parameter estimation loop enables the user to estimate model recharge parameters such as tributary underflow, percentage of canal leakage or aquifer recharge on non-irrigated lands along with the traditional model parameters of transmissivity and storativity.

Tool Use

The GIS Recharge Tool provides an analyst with a powerful tool for generation of model scenarios and different conceptual representations of aquifer recharge and discharge. The feature of the tool which allows a scenario to be based on an existing scenario enables the user to retain most of the input variables constant, varying only selected items, in order to test different conceptual models of recharge and discharge. This allows rapid generation of complex recharge/discharge scenarios for a ground water model, which is particularly useful during both model parameterization and model use.

In addition to generation of recharge and discharge for ground water models, the GIS Recharge Tool can be used to estimate the impacts to a regional aquifer from large-scale changes such as climate changes or changes in land use. By modifying the spatial inputs to the GIS Component, the user can create scenarios which represent significant changes in land use or natural precipitation or evaporation, then linking with the Fortran Component to predict the changes to aquifer recharge/discharge caused by these basin

changes. This makes the GIS Recharge Tool a powerful tool for assessing natural and management changes of a groundwater basin.

Determination of Source of Irrigation Water for Calibration of Eastern Snake Plain Aquifer Model Version 2

DESIGN DOCUMENT OVERVIEW

During calibration of the Eastern Snake Plain Aquifer Model Version 1.1 (ESPAM1.1), a series of Design Documents were produced to document data sources, conceptual model decisions and calculation methods. These documents served two important purposes; they provided a vehicle to communicate decisions and solicit input from members of the Eastern Snake Hydrologic Modeling Committee (ESHMC) and other interested parties, and they provided far greater detail of particular aspects of the modeling process than would have been possible in a single final report. Many of the Design Documents were presented first in a draft form, then in revised form following input and discussion, and finally in an "as-built" form describing the actual implementation.

This report is a Design Document for the calibration of the Eastern Snake Plain Aquifer Model Version 2 (ESPAM2). Its goals are similar to the goals of Design Documents for ESPAM1.1: To provide full transparency of modeling data, decisions and calibration; and to seek input from representatives of various stakeholders so that the resulting product can be the best possible technical representation of the physical system (given constraints of time, funding and personnel). It is anticipated that for some topics, a single Design Document will serve these purposes prior to issuance of a final report. For other topics, a draft document will be followed by one or more revisions and a final "as-built" Design Document. Superceded Design Documents will be maintained in a "superceded" file folder on the project Website, and successive versions will be maintained in a "current" folder. This will provide additional documentation of project history and the development of ideas.

INTRODUCTION

The ESPAM1.1 Design Document stated: "Recharge from surface-water irrigation is the largest component of aquifer recharge, and a large source of model uncertainty. The second-largest component of aquifer discharge is net withdrawals (calculated as consumptive use, or evapotranspiration) due to ground-water irrigation. The source of water for individual parcels must be identified so that diverted volumes of surface water are applied to the appropriate spatial locations" (Contor, 2004). Additional parameters for water-budget calculation, such as evapotranspiration adjustment coefficients, could potentially depend on the source of water assigned to a particular parcel.

EXHIBIT "515"
Page No. 2 of 15

Net extraction from ground-water pumping, on lands with no surface-water source, is calculated in the Recharge Tool using equation (1):

$$R_p = P - ET \quad (1)$$

Where R_p = net impact of pumping
P = precipitation
ET = crop evapotranspiration

In the Eastern Snake River Plain, precipitation is generally low enough that R_p is negative. Pumping is not explicitly represented; R_p implicitly includes gross pumpage and percolation returns to the aquifer. R_p is spatially distributed across the irrigated area, which is a reasonable approximation when the distance from wells to irrigated lands is small relative to model grid size, as is the case in the model grid used for ESPAM1.1.

Net recharge from surface-water irrigation is calculated in the Recharge Tool using equation (2):

$$R_n = (D - R - C + P_o + P - ET) \quad (2)$$

Where R_n = net recharge from irrigation
D = diversions from surface water
R = irrigation returns to surface water bodies
C = canal leakage separately represented[1]
P_o = offsite ground-water pumping separately represented[2]
(P and ET as defined above)

R_n is generally positive.

Careful inspection of equation (2) shows that if all the activities that do not occur on ground-water-irrigated parcels are set to zero, equation (2) is equivalent to equation (1) and can be validly applied to all irrigated lands.[3] If one considers a geographic region that includes the canals and offsite wells, equation (2) can be expanded to equation (3) to represent the full regional impact of irrigation

[1] Since canal leakage is represented elsewhere in the recharge tool as a recharge at the location of the leaky canal, this term does not change the water budget but simply adjusts the spatial distribution of recharge.
[2] Since offsite pumping is represented elsewhere in the recharge tool as an extraction at the location of the offsite well, this term also affects only the spatial distribution of impact.
[3] On an individual model cell, equations (1) and (2) are applied on a pro-rata basis according to irrigated acreage in each irrigation entity. On mixed source parcels, R_p is multiplied by the ground-water source fraction and R_n is multiplied by the surface-water-source fraction. Because of the way source fractions are used in calculating diversion depth for surface-water entities, the mass balance implied in equations (2), (3) and (4) is preserved for all irrigated lands.

EXHIBIT "515"
Page No. 3 of 15

upon the aquifer. The first set of parenthesis encloses on-farm impacts and the second set encloses off-farm activities.

$$R_n = (D - R - C + P_o + P - ET) + (C - P_o) \quad (3)$$

By combining like terms, equation (3) can be reduced to equation (4) which represents the regional net impact of irrigation, including ground-water, surface-water and mixed-source effects.

$$R_n = (D - R + P_o - ET) \quad (4)$$

This equation holds for a region as long as the four inputs on the right-hand side are correct. The location of ground-water-irrigated, surface-water-irrigated, and mixed-source parcels does not affect equation (4) nor the water budget, but simply the spatial distribution of R_n within the geographic region represented. With the current configuration of the Recharge Tool, this region is an irrigation entity.

Representation of the source of irrigation water in ESPAM1.1 was based on the authorized source of irrigation water according to Idaho Department of Water Resources water right, adjudication claim and adjudication recommendation data available in 2001 and 2002 (Contor, 2004). In ESPAM1.1, all parcels having only surface-water irrigation water rights were designated "surface-water irrigated," all parcels having only ground-water rights were designated "ground-water irrigated," and all parcels having both surface- and ground-water rights were designated "mixed source." On mixed-source lands, a fraction of supply was assigned to each source, with ground-water and surface-water fractions summing to 1.0 for each mixed-source parcel. A particular entity, for instance, might have a source fraction of 0.30 for ground-water irrigation and 0.70 for surface-water irrigation. Source fractions were based on surface-water diversion data and were assigned on an irrigation-entity-wide basis. The ESPAM1.1 Design Document (Contor, 2004) describes in more detail how the source fractions were determined and applied. Figure 1 shows the spatial distribution of ground-water fraction on mixed-source irrigated lands used in ESPAM1.1.

EXHIBIT "515"
Page No. 4 of 15

002365

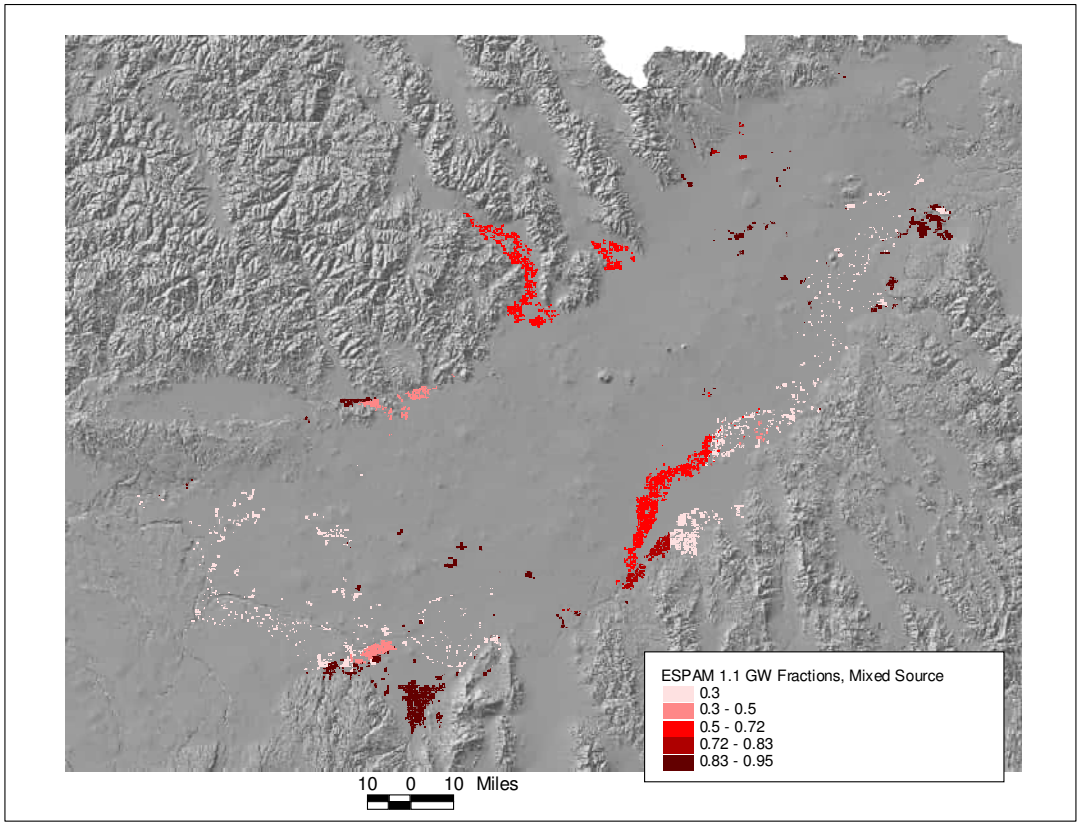

Figure 1. ESPAM1.1 ground-water fraction on mixed-source lands.[4]

During the fall of 2007, Idaho Water Resources Research Institute (IWRRI) reviewed aerial imagery, water rights GIS data and scanned images of paper water-right files for a statistical sampling of approximately 300 mixed-source irrigated parcels in south eastern Idaho, along with field inspection of a random sub-sample of parcels with access to Snake River water (Contor and others, 2008). An important outcome of this study was that very few parcels are physically mixed source; nearly all the parcels with both ground-water and surface-water rights are physically supplied from only one source or the other. This and other results are considered in light of the following questions for calibration of ESPAM2:

1. Is the ESPAM1.1 determination of source consistent with current water rights, claims and recommendations data?
2. Is there a possibility that the uniform representation of ground-water fraction across mixed-source irrigation entities distorts the representation of the impact of irrigation upon springs and reaches of the Snake River?
3. Can the source of irrigation water be represented with finer spatial resolution than was used in ESPAM1.1?

[4] Mixed-source lands that are served by wells for which actual diversion data are available are omitted from this figure. This affects organized irrigation companies in the Mud Lake area.

EXHIBIT "515"
Page No. 5 of 15

The first question is important because the first water-right determination was made during a period of rapid processing of claims, recommendations and partial decrees in the Snake River Basin Adjudication. Consequently, today's water-rights, claims and recommendations data bases are significantly different from those used in ESPAM1.1. One important difference is that many claims polygons used in ESPAM1.1 included detailed representation of individual parcels as either irrigated or not irrigated under a particular surface-water company or district's shares. However, in the process of the Snake River Basin Adjudication, many of these polygons have been superceded by large polygons that cast a broad boundary over entire service areas, obscuring the parcel-by-parcel detail that was present in the older data. This precludes simply repeating the analysis; if the ESPAM1.1 determination must be replaced, a new method, which will undoubtedly be more extensive and costly than the ESPAM1.1 evaluation, must be identified and applied.

The second question is whether the uniform representation of mixed-source lands distorts the spatial distribution of recharge. This is important because the primary purpose of ESPAM2 is to estimate impacts that stresses upon the aquifer (for instance, recharge or irrigation pumping) will have upon surface-water bodies. The process of calibration involves using known time series of impacts and known time series of spring discharges and river gains and losses. Figure 1 reveals that in ESPAM1.1, the ground-water extraction fraction was applied uniformly over large areas of mixed-source lands within some entities. The reality could be that there are discrete locations within these entities predominantly irrigated only by surface water, with other locations predominantly supplied from ground water. If true, this could distort the "known" data used to calibrate the model and therefore reduce the quality of the resulting calibration.

The third question is essentially a follow-up question to the second: Can we develop a more realistic method to represent the actual source of irrigation water on these mixed-source parcels?

This design document discusses these three questions and presents a proposal for the determination of source of irrigation water for calibration of ESPAM2. It is presented to provide transparency, stimulate discussion and seek input from the ESHMC.

APPLICATION OF DATA TO THREE QUESTIONS

Is the ESPAM1.1 Determination of Water Source Consistent With Current Data?

All the sample points were chosen to correspond to lands identified as "mixed source" in ESPAM1.1. Approximately seven percent of the sample points were in locations where gaps occurred in the water-rights GIS data (primarily

associated with lands under Native American sovereign jurisdiction). Of the remaining points, the current water-right status agreed with ESPAM1.1 determination on 88% to 95% of the points[5]. In every case, the change in status was due determinations made in the Snake River Basin Adjudication. Table 1 shows the status of the 24 points (5% to 12% of the total) where ESPAM1.1 disagreed with current data.

Table 1
Points where current data disagreed with ESPAM1.1 determination of water-right status. All points are on or very near the Eastern Snake Plain Aquifer.

ESPAM1.1	Current Data	No. Points
Mixed-source	Ground-water only	8
Mixed-source	Surface-water only	15
Mixed-source	No irrigation rights	1

Changes in the IDWR water-rights representation of canal company and irrigation district service areas indicate that repeating the analysis would require extensive effort. Discrepancies in identification of irrigation water source only introduce changes in spatial distribution of recharge and not in the water budget. Approximately 90% of the points for which a current water-right determination could be made agreed with the ESPAM1.1 determination of source. Therefore, it is proposed to use the ESPAM1.1 water-rights extraction as a basis for source maps for ESPAM2 calibration.

Does the current uniform representation of ground water on mixed-source lands distort spatial distribution of recharge within individual entities?

If a tract of mixed-source land the size of an irrigation entity had a concentration of ground-water irrigation in one location and a concentration of surface-water irrigation in another, the ESPAM1.1 representation of uniform distribution of ground water and surface water could represent a spatial distortion of recharge and discharge. Since ground-water irrigation depletes the aquifer during time periods when surface-water irrigation replenishes it, this distortion could adversely affect the ability of the model to match temporal variation in reach gains. During the January 2008 ESHMC meeting, participants identified Springfield, Idaho as the location where this effect would be likely to be of greatest concern within the study area, illustrated in Figure 2 (from Contor, 2008).

[5] The range is the alpha = 0.05 confidence interval for a binomial experiment (Snedecor and Cochran, 1980)

EXHIBIT "515"
Page No. 7 of 15

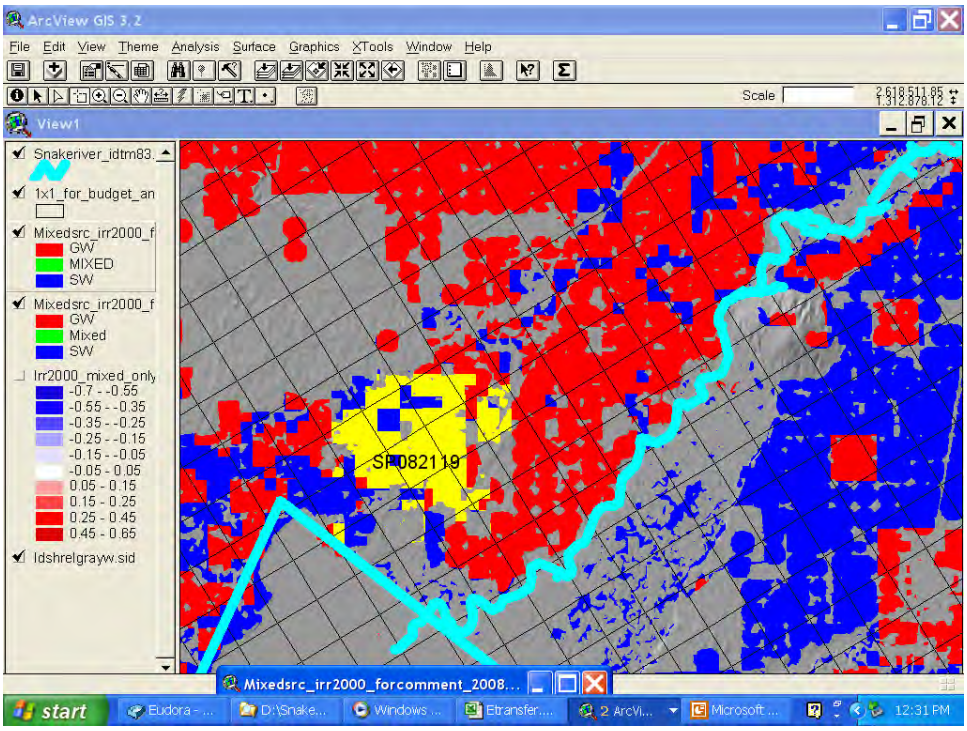

Figure 2. Yellow-coded lands are the subject of the test. Red (ground water) and blue (surface water) colors are preliminary determinations under "proximity" method.

The yellow-colored lands are the subject of the test. In ESPAM1.1 these were represented as mixed-source with uniform distribution of ground-water and surface-water irrigation according to the local irrigation entity's source fractions. Evidence suggests that in reality this area is predominantly ground-water irrigated. The analysis assumed the worst-case scenario, which would be that the lands colored yellow are actually irrigated solely from ground water. If that were the case, the estimated local distortion in stress due to the uniform representation of ESPAM1.1 could be two feet per year (Contor, 2008). A corresponding volume of water (based on irrigated acreage of the yellow-colored lands) was applied to the cell labeled in the Figure, using the Eastern Snake Plain Aquifer recharge tool (Cosgrove and others, 2007). The simulation results indicate that the distortion in representation of reach gains to the Near Blackfoot to Neeley reach of the river is about 12 cubic feet per second (cfs) in the summer, seven cfs in the winter and five cfs in the spring. This over-estimates the actual distortion, because the offsetting reductions that would occur elsewhere within the irrigation entity were not represented. Relative to total gains in the reach and uncertainties in the target data, this distortion is minimal. This test indicates the practical impact of the ESPAM1.1 simplification upon matching reach gains is minor. However, the impact on matching water levels in wells is also important.

Can the source of irrigation water be represented with finer spatial resolution than was done in ESPAM1.1?

To refine the spatial distribution of water source, a heterogeneous scheme of source fractions must be imposed on mixed-source lands within any given irrigation entity. Several possibilities exist, including the following (Contor, 2008):

1. A "proximity" method. Mixed source lands within 400 meters of an irrigation well[6] are deemed to be ground-water supplied and all others are deemed to be surface-water supplied.
2. A "dual radius" method. All mixed-source parcels within 100 meters of an irrigation well are deemed to be ground-water supplied, all parcels further than 1000 meters from an irrigation well are deemed to be surface-water supplied, and all other parcels are listed as "mixed-source undetermined," with the fraction of supply from ground water set at 50%.
3. "Dual 2," a modified dual radius method where all parcels within 100 meters of a well are assigned 90% ground-water source fraction, parcels further than 1000 meters are assigned a 10% ground-water fraction, and other mixed-source parcels are assigned 50%.
4. A "variable radius" method where the ground-water fraction of parcels ranges from 10% to 80% depending on distance from irrigation wells.[7]
5. A "no company" method where mixed-source lands are deemed to be surface-water irrigated if the ground-water right is in the name of a canal company or irrigation district, and deemed to be ground-water irrigated otherwise.

These methods all produce overall percentages of ground-water-only and surface-water-only parcels consistent with field inspection. The methods that assign parcels as solely ground water or solely surface water correctly represent up to 70% of individual parcels. This means, however, that they will be incorrect on 30% or more of individual parcels examined. This is probably too high an error rate from a perception standpoint. Based on this reasoning, the "proximity," "dual radius" and "no company" methods are rejected. Further, while the "no company" method produced a useful spatial distribution, assigning physical water source based on ownership could be construed to mean any number of things that the modeling project would certainly not intend to assert.

The "dual 2" and "variable radius" methods both avoid assigning any individual parcel as 100% ground-water irrigated or 100% surface-water irrigated. From a perception standpoint, the ground-water fraction on these parcels can be presented as a *probability* that an individual parcel is irrigated by ground water, rather than an actual determination for each parcel. The "dual 2" method is preferred above "variable radius" because it is more straightforward to apply.

[6] Irrigation wells are identified from IDWR water-rights GIS data available on the Internet.
[7] Zero to 100 meters = 80%, 900 to 1000 meters = 20%, over 1000 meters = 10%. Between 100 meters and 900 meters, the fraction is linearly interpolated between 20% and 80% at increments of ten percentage points.

EXHIBIT "515"
Page No. 9 of 15

Further, since it uses only three different percentages, it conveys the appropriate precision in our ability to estimate physical water source on a parcel-by-parcel basis.

OTHER CONSIDERATIONS

Source of irrigation water could be a required input for some model uses. Though not absolutely necessary, in model use it is attractive to use data and methods consistent with calibration. Of particular concern to the ESHMC is the use of water-source data in evaluation of potential administrative actions. In this context, some comparisons were made between the ESPAM1.1 representation and the alternate methods. Two points are important:

1. In any evaluation of administrative actions, the relevant irrigation water source will be the *post-action* condition. Proper evaluation of this must include adjustment for the expected response of owners of mixed-source lands to the administrative action. Even if current source fractions were perfectly represented in calibration data, these would not be likely to represent the post-action condition.
2. ESPAM1.1 represents the best effort at the time of the last calibration, but it is not a perfect representation. Comparisons between it and alternate methods are interesting, but simply finding a difference between ESPAM1.1 and an alternate method does not provide guidance for whether the alternate method should be adopted.

All the alternate methods reasonably represented the overall fraction of mixed-source parcels physically supplied by ground water. Figure 3 shows the comparison of acres in the vicinity of the Near Blackfoot to Neeley reach, a reach important to river gains. Figure 4 and Figure 5 compare the indicated effective ground-water acreage on mixed-source lands by entity, for the entire plain.[8]

[8] Figures 3 through 5 are from Contor, 2008.

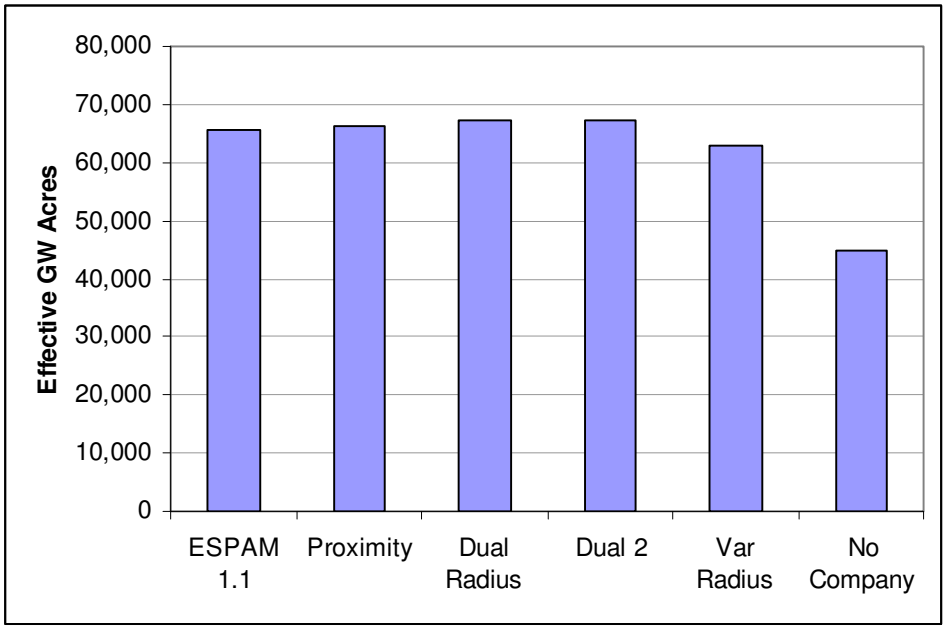

Figure 3. Effective ground-water acreage indicated on mixed-source lands in the vicinity of the Near Blackfoot to Neeley reach of the Snake River.

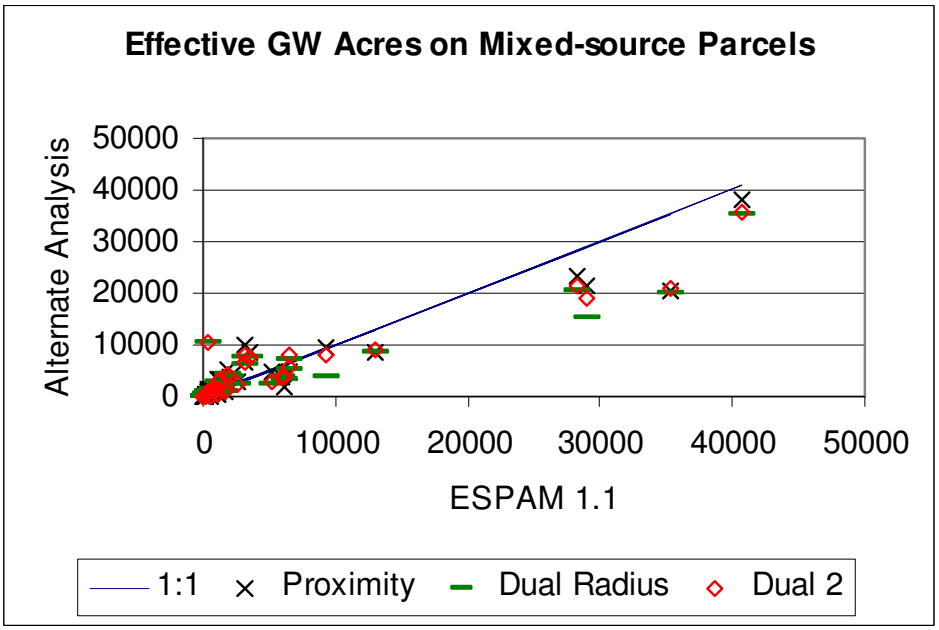

Figure 4. Cross Plot of total effective ground-water acreage by irrigation entity for alternate methods.

EXHIBIT "515"
Page No. 11 of 15

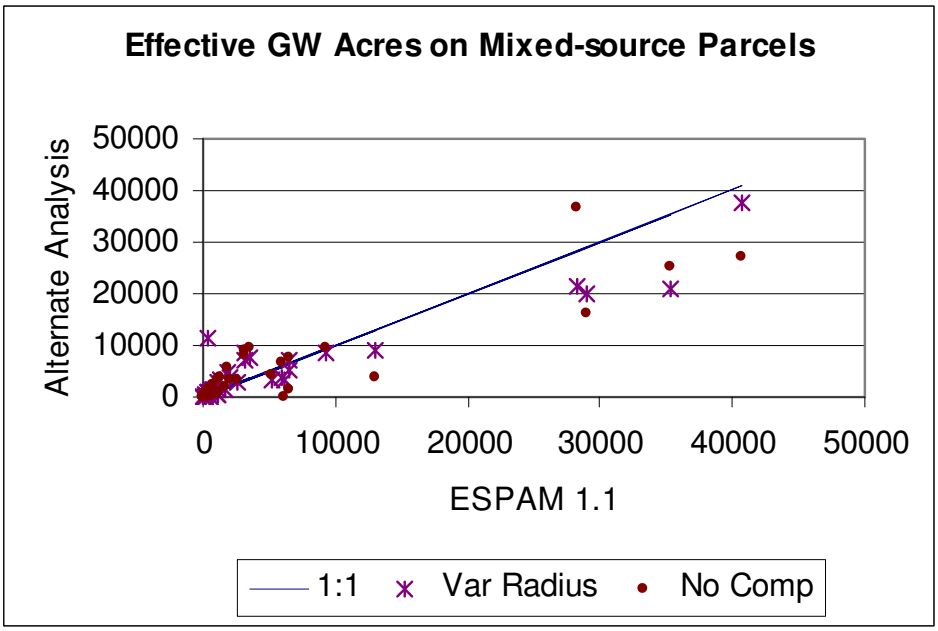

Figure 5. Cross Plot of total effective ground-water acreage by irrigation entity for alternate methods.

An additional consideration is that it would be desirable to identify a method that could be easily updated as new water-rights data become available. All the methods considered are essentially equivalent in this respect, though the "no company" method would require a small amount of hand processing.

DISCUSSION

In considering these results, several points are important:

1. The treatment of mixed-source lands will not affect the total calibration water budget.
2. The treatment of mixed-source lands will not change the distribution or allocation of water between irrigation entities.
3. The water budgets of individual irrigation entities will not change.
4. The only effect on calibration will be on the spatial distribution of recharge within each irrigation entity.
5. The ESHMC identified one location where the spatial distribution within an entity might make a difference in reach-gains matching. The test described above indicated that the potential effect is small.
6. More properly assigning source to individual parcels should aid in aquifer-head matching throughout the study area.
7. While comparisons with the ESPAM1.1 representation are interesting, we have no reason to believe the ESPAM1.1 representation is more correct than the alternate methods.

EXHIBIT "515"
Page No. 12 of 15

002373

It does not appear that there is any strong technical reason to favor any of the methods over another. However, perceptions of the resulting representations may be important. These favor the "dual 2" method.

DESIGN DECISION

It is proposed that the "dual 2" method be used to calculate the ground-water fraction on mixed-source lands for calibration of ESPAM2. Details include:

1. Lands identified as mixed-source in the ESPAM1.1 water-rights analysis will be represented as mixed-source in ESPAM2. Some manual adjustment will be made based on investigation of paper water-right files for suspect parcels. A list of adjustments made will be provided as an appendix to a revision of this design document.
2. The fraction of supply from ground water on mixed-source lands will be assigned according to proximity to irrigation wells in the current IDWR water rights, claims and recommendations data bases.
    a) Parcels within 100 meters of irrigation wells will be assigned 90% probability of being served by ground water (ground-water source fraction equals 90%).
    b) Parcels greater than 1000 meters from irrigation wells will be assigned 10% probability of being served by ground water (ground-water fraction equals 10%).
    c) All other mixed-source parcels will be assigned 50% ground water, 50% surface water.
3. The existing recharge-tool calculation methods will be retained.
4. As with ESPAM1.1, actual pumping and surface-water diversion data will be used to calculate the impact of mixed-source irrigation in the Mud Lake area, for parcels within organized companies and districts.

Figure 6 shows preliminary results of the proposed method in the Near Blackfoot to Neeley area. IWRRI requests input from the ESHMC on these proposals.

Re: Petition to Join Southwest Irrigation District

Dear Chairman and Board Members:

I am writing on behalf of McCain Foods USA, Inc. (the "Company") asking that the Company be allowed to join Southwest Irrigation District for mitigation as soon as possible. The water rights owned by the company and for which it is asking to be covered are listed below in Table 1.

As of the date of this letter, I understand via conversations with Mr. Higgs, that the rate for non-irrigation rights is $900.00 per cfs. He provided me with a spreadsheet of what he understood the costs would be to the Company. This spreadsheet is attached as Exhibit A. The Company is ready to remit payment as required by the Board in order to be covered by Southwest Irrigation District mitigation plan this year and as an ongoing member of the Irrigation District. Mr. Higgs indicated that the Board may consider asking the Company for back assessments. If the Board elects to charge back assessments, please let the Company know what those charges will be so that these additional charges can be considered and proper payment remitted. As you know, and as reflected in Exhibit A, the Company has not been using its most junior water rights for several years but under the Director's April 21, 2023, *Final Order Regarding April 2023 Forecast Supply* ("2023 As-Applied Order") its most senior water rights are now subject to curtailment. (See Table 1).

Water Right	PRIORITY DATE	OWNER	CFS	Water Use
45-2747	3/15/1960	MCCAIN FOODS USA INC	4.00	industrial
45-2748	3/6/1961	MCCAIN FOODS USA INC	0.60	industrial
45-2758	3/15/1960	MCCAIN FOODS USA INC	2.08	commercial
45-13970	9/1/1957	MCCAIN FOODS USA INC	2.66	industrial

Table 1.

Time is of the essence as the Company has a May 5, 2023 deadline to respond to IDWR's *Fifth Amended Methodology Order Regarding Methodology For Determining Material Injury to Reasonable In-Season Demand And Reasonable Carryover*, and *Final Order Regarding April 2023 Forecast Supply* ("2023 As-Applied Order"). Thus, the Company requests that a decision be provided as soon as possible and requests the Irrigation Districts' permission to inform the Idaho Department of Water Resources that we will be members of the Southwest Irrigation District and covered under its Mitigation Plan.

If you have any questions or concerns, please contact me at 208-870-3911 or 208-287-0991. Your prompt attention and consideration of this matter is greatly appreciated.

Sincerely,

Candice McHugh

Attorney for McCain Foods USA, Inc.

BEFORE THE DEPARTMENT OF WATER RESOURCES

OF THE STATE OF IDAHO

IN THE MATTER OF DISTRIBUTION OF WATER TO VARIOUS WATER RIGHTS HELD BY OR FOR THE BENEFIT OF A&B IRRIGATION DISTRICT, AMERICAN FALLS RESERVOIR DISTRICT #2, BURLEY IRRIGATION DISTRICT, MILNER IRRIGATION DISTRICT, MINIDOKA IRRIGATION DISTRICT, NORTH SIDE CANAL COMPANY, AND TWIN FALLS CANAL COMPANY	**Docket No. CM-DC-2010-001** **MCCAIN FOODS USA, INC.'S NOTICE OF MITIGATION**

REQUEST FOR HEARING

Pursuant to the *Final Order Regarding April 2023 Forecast Supply* ("2023 As-Applied Order") issued April 21, 2023 demand that:

> On or before May 5, 2023, ground water users holding consumptive water rights bearing priority dates junior to December 30, 1953, within the Eastern Snake Plain Aquifer area of common ground water supply shall establish, to the satisfaction of the Director, that they can mitigate for their proportionate share of the predicted DS of75,200 acre-feet in accordance with an approved mitigation plan.

McCain Foods USA, Inc., ("McCain") by and through its attorney of record, submits this *Notice of Mitigation*. McCain owns and uses water rights junior to the December 30, 1953,

date. On Tuesday, May 2, 2023 McCain petitioned Southwest Irrigation District ("SWID") to become a member of SWID and to be covered by its approved mitigation plan. Counsel for McCain was informed by letter on May 3, 2023, that McCain has been approved to join SWID as a member and that McCain will be covered under its mitigation plan. A copy of the letter is attached hereto as Exhibit A and incorporated herein. SWID also indicated that a letter was sent to IDWR informing IDWR of this fact.

McCain requests an order, or some other applicable document, from IDWR that it has established to the "satisfaction of the Director, that they can mitigation for their proportionate share … with an approved mitigation plan" by becoming members of SWID.

Submitted this 4th day of May, 2023

RE: Petition to Join Southwest Irrigation District for Mitigation

Dear Candice:

Pursuant to your request of May 2, 2023, the Board approved the mitigation for the following water rights:

WaterRight	Priority Date	Owner	CFS	Volume	Combined Limit	WaterUse	Condition
45-2747	3/15/1960	McCain Foods*	4.00	2062.80	-	Industrial	-
45-2748	3/6/1961	McCain Foods	0.60	309.40	-	Industrial	-
45-2758	3/15/1960	McCain Foods	2.08	1072.70	-	Commercial	-
45-13970	9/1/1957	McCain Foods	2.66	1371.80	-	Industrial	-
		Totals:	9.34	4816.70			

* McCain Foods USA Inc.

Southwest charges $900 per CFS per year billed in arrears.

It is the policy of Southwest Irrigation District to charge new participants in mitigation for the previous three years. In keeping with that procedure, the back fees for McCains would be $25,218.00. It may be paid over three years if necessary.

The 2023 assessment will be billed in the spring of 2024.

We have forwarded a letter to the Idaho Department of Water Resources indicating the

WAP/ar

approval of McCain Foods USA Inc. for mitigation.

I have sent a copy of this letter to you by email and I placed one in regular mail to your office.

Very truly yours,

PARSONS, LOVELAND, SHIRLEY & LINDSTROM, LLP

William A. Parsons
wparsons@pmt.org

From: Baxter, Garrick
To: Candice McHugh (cmchugh@mchughbromley.com)
Subject: McCain Foods
Date: Wednesday, May 24, 2023 9:55:52 AM
Attachments: image001.png

IDWR was able to confirm with Bill Parsons (attorney for SWID) that four rights in the name of McCain Foods were brought into SWID for mitigation:

- 45-2747
- 45-2748
- 45-2758
- 45-13970

IDWR also confirmed with Bill there are three other rights in the name of McCain foods that were NOT brought into SWID for mitigation.

- 45-2749, 8/13/1965, Industrial, 2.85 cfs, 734.7 acre feet
- 45-7137, 5/24/1973, Industrial, 3.43 cfs, 884.5 acre feet
- 45-7241, 5/27/1975, commercial & fire protection, 0.25 cfs, 72 acre feet

IDWR has updated its records to show that the four mitigated rights are covered by SWID. So long as SWID is in compliance with its approved mitigation plan, the four rights should be protected from curtailment.

Governor Brad Little Director Gary Spackman

May 1, 2023

RE: Notice of Possible Curtailment of Ground Water Rights with Priority Dates Junior to December 30, 1953 - Surface Water Coalition Delivery Call

Dear Water Right Holder,

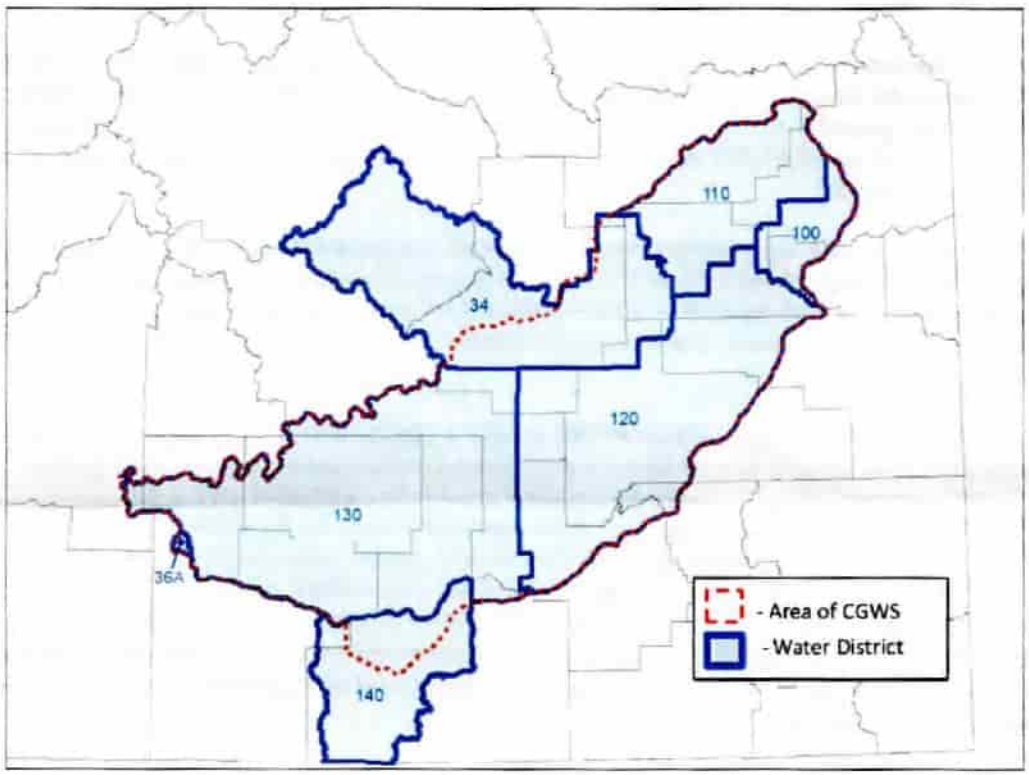
You are receiving this letter because, according to the records of the Idaho Department of Water Resources ("Department"), you are the holder of one or more water rights authorizing diversion of ground water from the Eastern Snake Plain Aquifer Area of Common Ground Water Supply ("ESPA") that are not covered by an approved and effectively operating mitigation plan. Because your water right(s) are not currently covered by an approved and effectively operating mitigation plan, **your water right(s) *may* be subject to curtailment this 2023 irrigation season.**

On April 21, 2023, the Director of the Department issued the *Final Order Regarding April 2023 Forecast Supply (Methodology Steps 1-3)* ("As-Applied Order"). The As-Applied Order predicts a shortfall in the water supply for senior priority Snake River water rights during the 2023 irrigation season, which will result in mitigation requirements or curtailment for ground water rights with priority dates junior to (later than) **December 30, 1953**.

The Department scheduled a hearing for the parties to the As-Applied Order on **June 6–10, 2023.** After the hearing the Director will decide whether to issue a curtailment order. If the Director issues a curtailment order, ground water rights junior to December 30, 1953, could be subject to curtailment unless the holders of junior priority ground water rights mitigate for ground water diverted pursuant to an approved mitigation plan.

Holders of ground water rights affected by a curtailment order may participate in an approved mitigation plan. See Idaho Code § 42-5259. If you are already a member of a ground water district, please contact and work with the district to ensure the district's records are up to date. If you are not a member of a ground water district, you may want to contact the nearest ground water district to inquire if the district will allow you to join.

Holders of ground water rights potentially subject to curtailment may also submit a proposed mitigation plan to the Director in accordance with Conjunctive Management Rule 43.[1] See IDAPA 37.03.11.043. However, please be aware the approval process for a mitigation plan is time-consuming. A proposed mitigation plan submitted now may not be approved in time for the 2023 irrigation season. Upon receipt of a proposed mitigation plan, the Director will publish notice for two successive weeks, after which ten days will be allowed for the filing of protests. The Director may hold a hearing if necessary to determine whether a proposed mitigation plan will mitigate injury to the SWC caused by diversions of ground water authorized by junior priority ground water rights. If the proposed mitigation plan is protested, the Director will hold a hearing. Please be advised that a curtailment order is not stayed pending evaluation of a mitigation plan.



[1] For example, a copy of the proposed mitigation plan submitted by the SWC & IGWA can be found here: https://idwr.idaho.gov/wp-content/uploads/sites/2/legal/CM-MP-2016-001/CM-MP-2016-001-20160309-SWCs-and-IGWAs-Stipulated-Mitigation-Plan-and-Request-for-Order.pdf

Information regarding the ongoing status of this matter may be found under the Current Topics section of the Department's website at: https://idwr.idaho.gov/ If you have questions concerning this notice, please contact the Department's State Office in Boise at 208-287-4800, or the water district watermaster in your area who regulates ground water within the ESPA and copied below. Water district boundaries can be found on the web at https://idwr.idaho.gov/water-rights/water-districts/map/, and Watermaster contact information can be found on the web at https://research.idwr.idaho.gov/files/ExternalReports/wdcontactsrpt.pdf

Re: Joining Magic Valley GWD

Dear Chairman and Board:

I am writing on behalf of the Amalgamated Sugar Company (the "Company") asking that the Company be allowed to join Magic Valley Ground Water District as a mitigation only member effective immediately. The water rights owned by the company and for which it is asking to be covered are listed below:

Water Right No.	Priority Date	CFS	Use
36- 2237	11/14/1953	3.32*	COMM, COMM
36- 2238	11/14/1953	3.77*	COMM
36- 2271	11/15/1954	3.77*	COMM
36- 2272	11/15/1954	4*	COMM
36- 4144	3/1/1953	0.48	COMM
36- 4145	3/3/1956	0.69*	COMM
36- 4178	6/1/1959	0.01	COMM
36- 4254	3/20/1961	0.09	INDUST
36- 4255	11/15/1956	0.2	INDUST
36- 8364	6/10/1988	0.22	INDUST
	TOTAL CFS	5.46	

* Combined limit of 4.46

Water Right Nos. 36-2237, 36-2238, 36-2271, 36-2272 and 36-4145 have combined use limitations of 4.46 cfs. Thus, making the total 5.46 cfs for the water rights owned by the company within Basin 36.

As of the date of this letter, I understand that the rate for non-irrigation rights is $1,113.00 per cfs. The Company is ready to remit payment for the assessment to be covered by Magic Valley GWD's mitigation plan and requests that it not have to pay for back assessments. However, in

the event the Board elects to charge back assessments, please let the Company know what those charges will be so that these additional charges can be considered and remitted.

you know, time is of the essence and the Company has a May 5, 2023, deadline coming up this Friday to respond to IDWR's *Fifth Amended Methodology Order Regarding Methodology For Determining Material Injury to Reasonable In-Season Demand And Reasonable Carryover*, and *Final Order Regarding April 2023 Forecast Supply* ("2023 As-Applied Order"). Thus, the Company requests that a preliminary decision be given along with the required payment as soon as possible and have the Ground Water District's permission to inform the Idaho Department of Water Resources that we will be members of the Magic Valley Ground Water District.

If you have any questions or concerns, please contact me at 208-870-3911 or 208-287-0991. Your prompt attention and consideration of this matter is greatly appreciated.

sincerely,

Candice McHugh

Attorney for Amalgamated Sugar Company

BEFORE THE DEPARTMENT OF WATER RESOURCES

OF THE STATE OF IDAHO

IN THE MATTER OF DISTRIBUTION OF WATER TO VARIOUS WATER RIGHTS HELD BY OR FOR THE BENEFIT OF A&B IRRIGATION DISTRICT, AMERICAN FALLS RESERVOIR DISTRICT #2, BURLEY IRRIGATION DISTRICT, MILNER IRRIGATION DISTRICT, MINIDOKA IRRIGATION DISTRICT, NORTH SIDE CANAL COMPANY, AND TWIN FALLS CANAL COMPANY	**Docket No. CM-DC-2010-001** **AMALGAMATED SUGAR COMPANY'S REQUEST FOR HEARING, OBJECTION, IDENTIFICATION OF ISSUES AND NOTICE OF MITIGATION**

REQUEST FOR HEARING

Pursuant to Idaho Code § 42-1701(A)(3), Amalgamated Sugar Company ("Amalgamated") through its undersigned attorney, requests a hearing on the Department's *Fifth Amended Methodology Order Regarding Methodology For Determining Material Injury to Reasonable In-Season Demand And Reasonable Carryover* and *Final Order Regarding April 2023 Forecast Supply* ("2023 As-Applied Order") both issued April 21, 2023.

OBJECTION TO ORDER

Amalgamated objects to the *Fifth Amended Order* and the 2023 As-Applied Order's implementation this upcoming season for the reasons set forth below which it also identifies as issues for hearing. Amalgamated reserves the right to revise the issues as more information becomes available.

STATEMENT OF ISSUES FOR HEARING

Among the issues the Amalgamated has identified for hearing are:

a) IDWR's new reliance on transient modeling;

b) IDWR's failure to consider the Twin Falls Canal Company's increase in diversions over the last twenty years;

d) IDWR's failure to consider changes in the efficiency of the SWC's operations;

e) IDWR's failure to consider all sources of supply available to the SWC;

f) IDWR's use of 2018 as the new baseline year; and

g) IDWR's violation of Amalgamated's due process rights by not providing it actual notice of the order and requisite deadlines, and even if it was deemed that it was given "notice" because it shared an attorney with the Coalition of Cities, by giving it less than 10 business days to provide a mitigation solution after a wholesale change in methodology, by depriving it of the ability to develop its own mitigation plan to protect its water rights, by requiring compliance with a deadline to avoid curtailment without actual notice of the deadline and in a non-drought year, by setting the hearing without regard to the time required for discovery and without consideration of the existing obligations of the parties, their legal representatives and consultants.

NOTICE OF MITIGATION

Pursuant to the *Final Order Regarding April 2023 Forecast Supply* ("2023 As-Applied Order") issued April 21, 2023 demand that:

> On or before May 5, 2023, ground water users holding consumptive water rights bearing priority dates junior to December 30, 1953, within the Eastern Snake Plain Aquifer area of common ground water supply shall establish, to the satisfaction of the Director, that they can mitigate for their proportionate share of the predicted DS of 75,200 acre-feet in accordance with an approved mitigation plan.

Amalgamated submits this *Notice of Mitigation*. Amalgamated owns and uses water rights junior to the December 30, 1953, date. On Tuesday, May 2, 2023 Amalgamated petitioned Magic Valley Ground Water District ("MVGWD") to become a member of MVGWD and to be covered by its approved mitigation plan. Counsel for Amalgamated was informed by the Chairman of MVGWD, Dean Stevenson, that the letter had been received, that he had spoken to the board members and that they will take up Amalgamated petition at its Tuesday, May 9, 2023 meeting. Chairman Stevenson also indicated to counsel for Amalgamated that he expected the petition to be approved on Tuesday and that MVGWD would send a letter to IDWR and Amalgamated' s counsel to that effect next week. Aff. of McHugh filed herewith.

Amalgamated requests an order, or some other applicable document, from IDWR that it has met the May 5, 2023 deadline and established to the "satisfaction of the Director, that they can mitigation for their proportionate share … with an approved mitigation plan" by becoming members of MVGWD.

Submitted this 4th day of May, 2023

Candice,
IDWR spoke to Ryan Shurtliff of Water Well Consultants who are consultants for Magic Valley Ground Water District. Ryan confirmed Amalgamated has joined the ground water district for the following ten water rights:

- 36-2237
- 36-2238
- 36-2271
- 36-2272
- 36-4144
- 36-4145
- 36-4178
- 36-4254
- 36-4255
- 36-8364

IDWR has updated its records to show Amalgamated has joined MVGWD. These water rights will not be subject to curtailment so long as MVGWD is in compliance with an approved mitigation plan.

IDWR did identify three other water rights: 29-14014, 35-13990, 45-13580. Two rights are in the name of "Amalgamated Sugar Co LLC" and one right is in the name of "The Amalgamated Sugar Co LLC." IDWR's records show that two of these rights are part of IGWA through the American Falls-Aberdeen GWD, and the other right being covered by Southwest Irrigation District. Can you confirm that these rights continue to be part of AFAGWD and SWID?

1 Introduction

This report has been prepared on behalf of the Idaho Groundwater Appropriates Inc., ("IGWA") in connection with the *Fifth Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover* ("*Fifth Methodology Order*") and the *Final Order Regarding April 2023 Forecast Supply* ("*April 2023 As-Applied Order*") issued by the Director of the Idaho Department of Water Resources ("IDWR" or "Department") on April 21, 2023.

The *Fifth Methodology Order* defines the process and calculations utilized by the Director to predict material injury incurred by the Surface Water Coalition ("SWC"). The SWC comprises A&B Irrigation District ("A&B"), American Falls Reservoir District #2 ("AFRD2"), Burley Irrigation District ("BID"), Milner Irrigation District ("Milner"), Minidoka Irrigation District ("MID"), North Side Canal Company ("NSCC") and Twin Falls Canal Company ("TFCC"). The *April 2023 As-Applied Order* implements steps 1-3 of the Fifth Methodology Order to the conditions in existence at the beginning of the 2023 irrigation season.

The SWC entities divert surface waters of the Snake River at Minidoka Dam and Milner Dam. In 2005, the SWC filed a petition ("delivery call") with the Director seeking curtailment of junior-priority ground water rights that allegedly cause depletions of the Snake River and material injury to the SWC. The petition is governed by IDWR's Rules for Conjunctive Management of Surface and Ground Water Resources ("Conjunctive Management Rules) (IDAPA 37.03.11).

After an evidentiary hearing held in 2008, the hearing officer issued an *Opinion Constituting Findings of Fact, Conclusion of Law and Recommendations* on April 29, 2008 ("Hearing Officer Recommendation"). On September 5, 2008, the Director issued a final order in this matter ("2008 Final Order"), in which he ruled on all issues raised at the hearing with the exception of stating his methodology for determining material injury to the SWC reasonable in-season demand ("RISD") and reasonable carryover. On April 7, 2010, the Director issued the *Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover ("First Methodology Order")* setting forth the methodology for calculating material injury to RISD and reasonably carryover. A series of amendments to the First Methodology Order were made in subsequent years.

From 2016-2022, the Director administered water rights under the *Fourth Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover* ("*Fourth Methodology Order*"). On April 21st, 2023, the Director issued the *Fifth Methodology Order.* This expert report addresses changes made to the methodology in the *Fifth Methodology Order*, as well as the implementation of the new methodology in the *April 2023 As-Applied Order*, in preparation for a hearing currently scheduled for June 6-10th, 2023, concerning these orders.

In forming my opinions I have relied on review of the First Methodology Order and subsequent amendments thereto, my participation in the SWC Methodology Technical Working Group (TWG) meetings held by the Department in 2015 and 2022, my participation since 2012 as a member of the Eastern Snake Hydrologic Modeling Committee (ESHMC) which gives technical support to the Department on the development of the Eastern Snake Plain Aquifer Model (ESPAM), and my professional expertise as a hydrologist and groundwater modeler. I have examined maps and cross-sections of portions of the Eastern Snake Plain Aquifer (ESPA) and tabulations and diagrams of ESPA water rights, and I have drawn upon my accumulated knowledge of the water rights and hydrology of

the ESPA. To the extent that other information becomes available, the Director or the Department modifies any information presented, or new analysis and information becomes available, I reserve the right to modify or expand upon my opinions related to this case.

1.1 Report Organization

This report is organized into 5 sections, beginning with this introduction. Section 2 presents analysis and opinions related to the Fifth Methodology and the April 2023 As-Applied Order, including components of the RISD calculation involving irrigated acres, baseline year, and reasonable carryover. Section 3 discusses the simulation of curtailment of junior groundwater rights using the ESPAM model, including background and overview of the ESPAM model development, calibration, uncertainty, and recommendations for its application in the Fifth Methodology Order. Section 4 is a summary of my conclusions, and section 5 presents sources of information relied upon for my analysis.

2 Director's Methodology and As-Applied Order

2.1 Reasonable In-Season Demand (RISD)

2.1.1 Background

The First Methodology Order laid out the Director's methodology for determining material injury to SWC's Reasonable In-Season Demand (RISD) and Reasonable Carryover. The First Methodology Order provides a brief overview of the methodology for RISD starting with paragraph 11, explaining that material injury is the product of the SWC's predicted water supply and predicted water demand stating:

> In-season demand shortfalls will be computed by taking the difference between the RISD and forecast supply ("FS"). Initially RISD will be equal to the historic demands associated with a baseline year or years ("BLY") as selected by the Director, but will be corrected during the season to account for variations in climate and water supply between the BLY and actual conditions. The above description is represented by the following equation:
>
> In-Season Demand Shortfall = RISD – Forecast Supply (FS)

In April, at the start of the irrigation season, RISD is determined solely by the BLY. As the irrigation season progresses, weather and canal system operations are taken into account to make adjustments to RISD according to the following equation:

$$(1)\ RISD_{milestone_x} = \sum_{j=1}^{m}\left(\frac{CWN_j}{E_{p_j}}\right) + \sum_{j=m+1}^{7} BD_j$$

Where:

$RISD_{milestone_x}$ = reasonable in-season demand at specified evaluation milestones during the irrigation season,
CWN = crop water need for month, j
E_p = baseline project efficiency for month j,
BD = baseline demand for month j,
j= index variable , and
m= upper bound of summation, equal to the month calculation occurs, where April =1, May =2, … October -7

Crop Water Need ("CWN") is the project-wide volume of irrigation water required for crop growth as calculated by the following equation:

(2) $CWN = \sum_{i=1}^{n}(ET_i - W_e)A_i$

Where:

CWN= crop water need,
ET_i= consumptive use of specific crop type,
W_e= estimate effective rainfall,
A_i= total irrigated area of specific crop type,
I= index variable representing the different specific crop types grown within the irrigation entity, and
n=upper bound of summation equal to the total number of different specific crop types grown within the irrigation entity.

2.1.2 Irrigated Acres

2.1.2.1 Background on Irrigated Acres

For the purpose of water rights administration, the Hearing Officer stated in the Hearing Officer's Recommendation at page 53 states: "Non-irrigated acres should not be considered in determining the irrigation supply necessary for SWC members." This recommendation was adopted in the 2008 Final Order, and was sustained on appeal. Accordingly, the First Methodology Order, paragraph 25 states:

> Estimates of irrigated acres from the hearing show a trend of decreasing irrigated acreage. R. Vol. 28, 5205-15; R. Vol. 37 at 7100. According to the Hearing Officer, beneficial use cannot occur on acres that have been hardened or are otherwise not irrigated. R. Vol. 37 at 7100.

2.1.2.2 2015 TWG regarding Irrigated Acres

On January 30, 2015, the Director instructed Department staff to convene a committee to recommend specific technical changes to the *Second Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-season Demand and Reasonable Carryover ("*Second Methodology Order") issued June 23, 2010. The Director requested improvements to the following components of the methodology:

1) Revising natural flow forecast methods for Twin Falls Canal Company.
2) Identifying more accurate and current crop data to determine crop water need.
3) Improving the mid-season reasonable in-season demand forecast.

In response, Department employee Matt Anders gave a presentation on February 19, 2015, to outside consultants, referred to as the Technical Working Group ("TWG"), titled *Proposed Modification to Method for Determining Reasonable In-Season Demand for the Surface Water Coalition: Irrigated Acres for SWC Members*. Table 2-1 shows the actual irrigated acres of each SWC entity presented to the TWG. The TWG was also provided a spreadsheet titled "DS_RISD Calculator_2014" with data used to

calculate the DS and RISD which included a summary of irrigated acres utilized in Protocol Calculations as shown in Table 2-2.

The acreage figures shown for BID, MID, and TFCC reflect the evidence that Scott King with SPF Water Engineering[1] provided at the evidentiary hearing in 2008 which analyzed hardened acres. It was my understanding in 2015 that these would be the irrigated acres used in the Methodology Order. However, my recent review of the Department's RISD calculation spreadsheet indicates that these acres were only applied to calculations 2000-2014. Note that the Methodology was not adopted until 2010 but the Department's RISD calculation sheet includes a hindcast starting in 2000.

In the Department staff presentations to the 2015 TWG it was made clear that the Department had not adopted any type of process for reviewing the irrigated acre figures reported annually by the SWC. Consequently, there was no incentive for SWC entities to keep an accurate accounting of irrigated acres, and few SWC entities provide annual updates to their irrigated acreage figures; most simply report that there has been no change in irrigated acreage. To ensure that the Department does not include non-irrigated acres in its calculation of RISD, I submitted comments to the TWG in 2015 stating that irrigate acres should by verified using satellite and/or aerial imagery. A copy of my comments in 2015 is included as ATTACHMENT A.

Table 2-1. Summary of SWC irrigated acres 2015 TWG.

SWC Member	2005-2007 SPF	2012 Partial Decrees	2013 SWC Submitted Shapefiles	2013 RISD

NSCC	154,067	5/11/2006	Director's Report

*For A&B the "area of surface water irr" value (15,924 ac) includes 1,176 enlargement acres that were included in the Department's recommendation.

Among the documents produced by the Department in connection with the upcoming hearing concerning the Fifth Methodology Order is a document titled *"DRAFT_SWC_Mapping_Procedures_Revised_Nov2014_v2_matt"* which appears to have been created in preparation for the 2015 TWG. The stated purpose of the document is to map the irrigated land for each of the seven SWC entities and establish a procedure for reviewing irrigated lands data submitted by SWC entities and for utilizing irrigated lands data developed by IDWR if SWC members do not submit irrigated lands data. The document indicates that irrigated lands data developed by IDWR will be used if SWC members do not submit irrigated lands data. It further indicates that as of October 2014, the latest irrigated lands data is from 2010. The document identifies information that may be utilized to identify actual irrigated acreage including the Place of Use (POU) of water rights with surface water as a source, POU of water rights with groundwater as a source, and the most recent Crop Data Layer (CDL) developed by USDA NASS which is released January for the previous year.

Under "Background Information" the document notes that irrigated lands data is not submitted by SWC members on an annual basis. That the last data for BID, MID, and TFCC is from 2013, and it does not indicate whether the source is surface water, groundwater, or mixed source. The document notes that the irrigated acres can change slightly from year to year because of permissible POU but that these should be minor changes. It also recommends that supplemental groundwater use be addressed, identifying the GIS 2006 groundwater and mixed source data layer used in ESPAM as a potential source of such information.

Consistent with this document, the irrigated acreage information in Table 2-1 was presented to the 2015 TWG with the inference that it would be utilized in the RISD component of the methodology. The use of the CDL USDA NASS data for crop mix was also presented and recommended by Department staff for incorporation in the RISD calculation. Department staff ultimately determined there was insufficient time for the committee to evaluate supplemental groundwater use given the extremely compressed timeframe of the 2015 TWG.

2.1.2.3 2022 TWG regarding Irrigated Acres

In a status conference held August 5, 2022, the Director issued a directive to Department staff to convene a TWG to review and provide comments on potential technical changes to the Fourth Methodology Order. Department staff were again tasked with RISD refinements, and Department staff presented some of their analysis on the differences between the current RISD method for CWN employing USDA NASS CDL data compared to Near Real Time METRIC (Mapping EvapoTranspiration at high Resolution and Internalized Calibration).

On November 17, 2022, Department staff gave a presentation on Near Real Time METRIC which included, as slide 6, an outline of the current method for calculating CWN, including "Remove non-irrigated land from CDL using the IDWR Irrigated Lands Dataset." Near Real Time METRIC provides a high-resolution data set that documents irrigated acreage in "near real time," making accurate irrigated acreage data available from the previous irrigation season and potentially in the current season.

However, in a subsequent presentation given on December 1, 2022, titled *Proposed Modification to Method for Determining Reasonable In-Season Demand for the Surface Water Coalition: Use of the Near Real Time Metric*, the acreage information shown in Table 2-3 was presented.

Table 2-3. Summary of SWC irrigated acres 2022 TWG.

SWC Member	Shapefile Acres	If Removed Non-Irrigated Acres with 2011 Irrigated Lands Dataset (IDWR)	If Removed Non-Irrigated Acres with 2017 Irrigated Lands Dataset (IDWR)	NRT METRIC Processing Acres 2021 (IDWR)	Methodology Acres
A&B	21,976 (PPU, 2010)	21,585	21,634	21,625	15,924 (SRBA Partial Decree)
AFRD2	69,279 (PPU, 2010)	68,368	66,606	68,384	62,361 (SRBA Partial Decree)
Burley	46,035 (SWC, 2013)	44,113	44,168	44,139	46,035 (SWC, 2013)
Milner	14,844 (PPU, 2010)	13,239	13,202	13,233	13,335 (SRBA Partial Decree)
Minidoka	75,340 (SWC, 2022)	71,295	72,016	71,073	75,340 (SWC, 2022)
NSCC	224,463 (PPU, 2010)	220,935	218,498	220,937	154,067 (SRBA Partial Decree)
TFCC	194,732 (SWC, 2013)	179,486	180,956	179,456	194,732 (SWC, 2013)

It became clear from this presentation that since 2015 the Department has not utilized the most accurate irrigated acreage data to calculate RISD, but has instead utilized the lesser of either the decreed acreage or the acreage reported by SWC, without making any effort to insure that non-irrigated acres are not being accounted for in the IDWR's calculation of RISD. The Department's RISD calculation sheet show that the "Methodology Acres" from Table 2-3 are used in calculation of CWN 2015-2022.

Department staff could not explain why the more accurate and reliable acreage data was not being used in the methodology.

Every technical analysis of irrigated acres consistently shows that TFCC is irrigating approximately 15,000 acres less than the 194,732 acre figure that TFCC reports to IDWR as being irrigated. The expert report of SPF Water Engineering submitted in 2008, IDWR's irrigated lands data sets from 2011 and 2017, and Near Real Time METRIC data from 2021, consistently demonstrate actual irrigated acreage of approximately 180,000 acres. (The IDWR irrigated lands data sets and Near Real Time METRIC are discussed further below.) It is clear that the Department is not using the best science available to determine irrigated acres in the Fifth Methodology Order, relying instead on outdated acreage figures provided by the SWC entities.

2.1.2.4 IDWR's High Resolution Irrigated Lands Dataset

The IDWR has invested years of time and staff to produce a large archive of high-resolution irrigated lands data. IDWR's Irrigated Lands dataset is a three-class land-use classification including irrigated, semi-irrigated and non-irrigated areas. This data set was developed at the request of the ESHMC. It is used to calculate the ET and consumptive use components that make up one of the most important input parameters to the ESPAM. Irrigated lands acreage, as defined by the IDWR Irrigated Lands dataset, directly affects the volume of evapotranspiration (ET) in the ESPAM model. Similarly, irrigated acreage directly affects the volume of ET used to calculate RISD.

IDWR's Irrigated Lands data set utilizes satellite imagery, National Agricultural Imagery Program (NAIP) imagery, Digital Orth Photo Quadrangle (DOQQ) imagery, and other in-house, scanned aerial imagery for determining irrigation status. Attribute assignment for the irrigation status (irrigated, non-irrigated, and semi-irrigated) is determined using satellite imagery. Landsat and Sentinel Imagery provides the analyst the ability to monitor ground, moisture, and vegetation conditions over the entire growing season. Hand digitizing field boundaries using the satellite data and imagery produces a very accurate and precise depiction of irrigated acres.

In conjunction with the image data, IDWR analysts use Common Land Unit (CLU) polygons of individual fields that were digitized from the National Agricultural Inventory Program (NAIP) imagery by the Farm Services Administration (FSA). IDWR uses the unattributed CLU polygons because they are an existing, recent, highly-detailed, vector dataset the IDWR could attribute easily as irrigated or non-irrigated. These polygons were then hand edited when IDWR began working with the CLU data. IDWR then goes through a three-step classification (Figure 2-1) where step 1) used Landsat satellite data, 2) used a combination of Landsat and NAIP digital photography, and 3) used NAIP photography and CLU data.

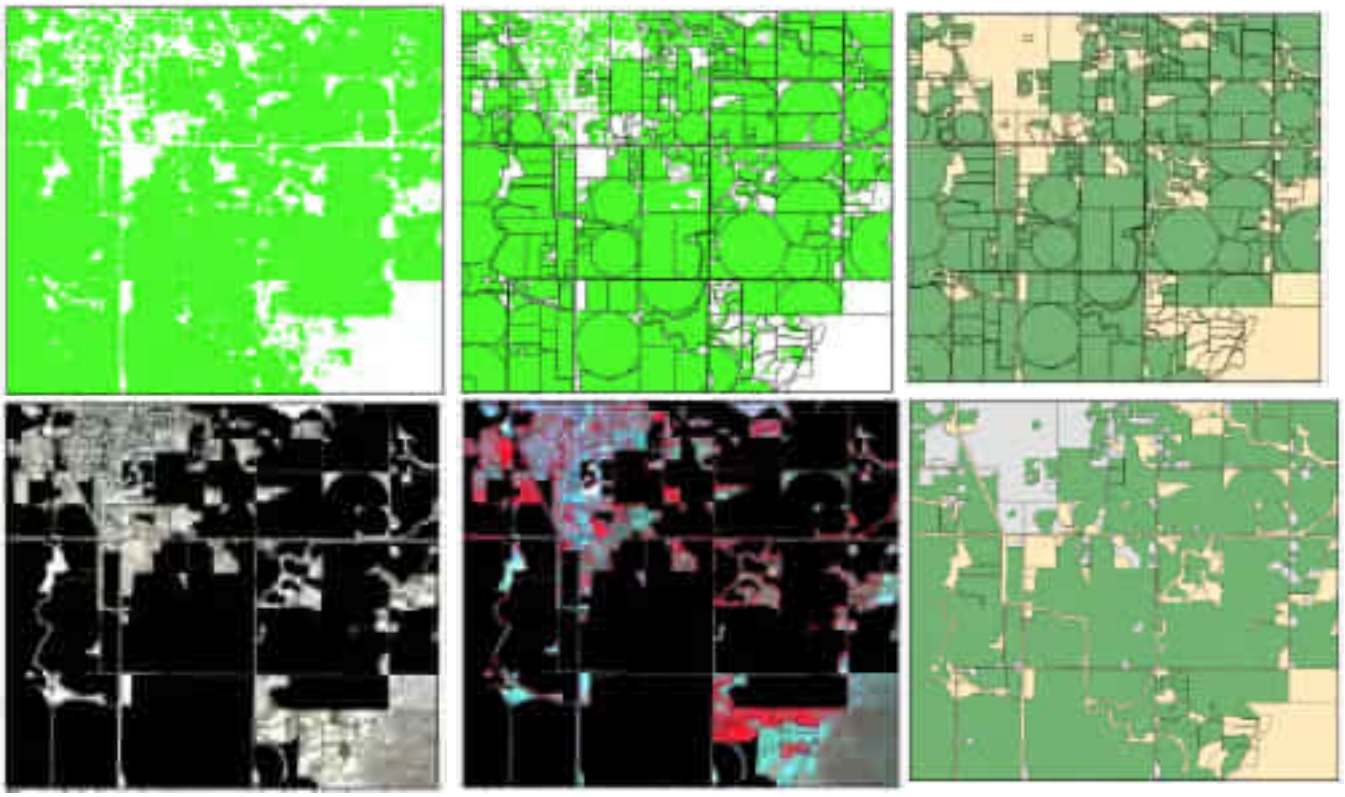

Figure 2-1: Sequence of IDWR Irrigated Land dataset processing from top left to bottom right 1)initial landsat-based classification out, 2) Landsat output with CLU polygons superimposed, 3) initial CLU polygon classification from irrigated (green) or non-irrigated based on 75% or greater rule, 4) irrigated polygons masked to black and superimposed on NAIP image, 5) irrigated polygons masked black and superimposed on Landsat data, 6) final edit classification with irrigated in green, non-irrigated in beige, and semi-irrigated (residential) in gray. (Source 2006 Irrigated Land Classification for the Eastern Snake Plain Aquifer Model, IDWR)

IDWR Irrigated Lands data sets for the ESPA include 1986, 1996, 2000, 2002, 2006, 2008, 2009, 2010, 2011, 2012, 2013, 2014, 2015, 2016, and 2017. Department staff have reported that the Irrigated Lands data set 2021 could be complete by next year.

2.1.2.5 IDWR METRIC Dataset

IDWR and the University of Idaho worked under a NASA grant to develop the procedures to map ET from satellite data (Landsat) for water resources applications. The METRIC energy balance model was developed to compute and map ET using Landsat images. Dr. Rick Allen, Dr. M. Tasumi, and Dr. R. Trezza, of the University of Idaho, developed METRIC by making refinements to the Surface Energy Balance Algorithm for Land (SEBAL). Landsat measures visible, near-infrared, and thermal infrared radiation and has a pixel size small enough to map individual agricultural fields. METRIC also incorporates USBR AgirMet weather data into the modeling process. IDWR uses METRIC data (in years it is available) to calculate the ET rate for the ESPAM model (Figure 2-2). METRIC ET maps for eastern southern Idaho have been generated for 1986, 1996, 2000, 2006, 2008, 2009, 2010, 2011, 2013, 2016, 2017 and 2018. The partnership is also responsible for the NRT METRIC processing for 2019, 2020, and 2021.

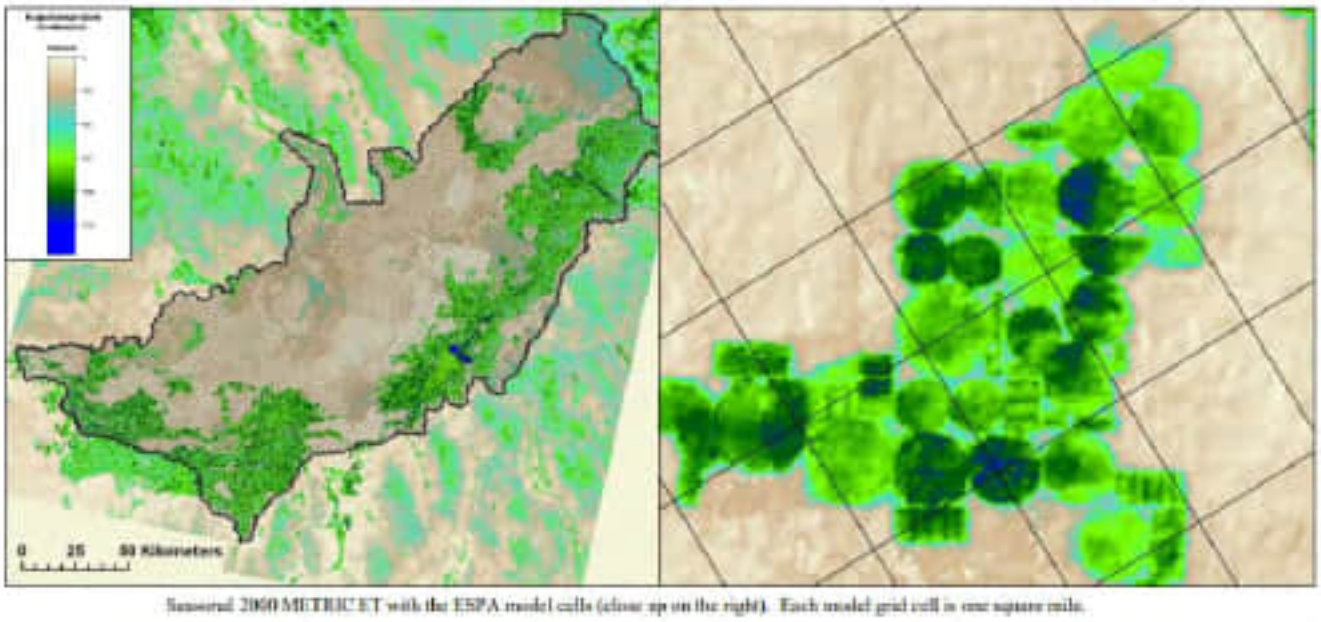

Figure 2-2: Example of seasonal 2002 METRIC ET within the ESPAM boundary (close up on the right). Each model grid cell is one square mile (Source IDWR Mapping Evapotranspiration; Hydrological Modeling https://idwr.idaho.gov/gis/mapping-evapotranspiration/).

2.1.2.6 Conclusions Regarding Irrigated Acres

The presentation by IDWR staff in November 2022 regarding NRT METRIC application revealed a significant shortcoming in the Fourth Methodology Order in that SWC irrigated acre datasets sometimes represent service areas as opposed to the actual irrigated land. If non-irrigated acres are to be excluded in calculating RISD, the Department should implement a review process in Step 1 of the Methodology Order that compares the irrigated acreage figures reported by SWC entities with the irrigated acreage data in the most recent Irrigated Lands data set and METRIC data. In any case, the Department should use the most accurate and reliable source of irrigated acreage data to calculate RISD in the Methodology Order.

As mentioned above, the most recent Irrigated Lands data set and the most recent METRIC data show that actual irrigated acreage within TFCC is approximately 15,000 acres less than the 194,732 acre figure that TFCC reports as irrigated. If the NRT METRIC acreage figure of 179,456 irrigated acres is utilized in the Department's RISD calculation sheet for 2022, the "Actual November Shortfall" calculated is reduced by 84,732 acre-feet (af). This underscores how critical it is that IDWR use care to identify actual irrigated acreage and calculate RISD based on actual irrigated acreage.

The Department's use of outdated irrigated acreage data highlights another problem of the Methodology Order relying on inferior data. The ESPAM is considered the best science available, and it utilizes the IDWR Irrigated Lands datasets and METRIC to calculate ET along with PRISM (Parameter-elevation Relationships on Independent Slopes Model) for precipitation. By contrast, in addition to using outdated irrigated acreage data, the Methodology Order uses an outdated approach with CDL data for crop mix, and Agrimet station data for the ET rate and precipitation. The ESPAM model also uses IDWR's determination for mixed sources lands where a groundwater fraction is applied on lands that have been designated as irrigated by both surface water and groundwater. The Fifth Methodology Order does not distinguish mixed source lands.

2.1.3 Baseline Year

In the First Methodology Order the BLY is characterized as a year or group of year(s) where water demands and water supplies can be used to as a benchmark to predict water demands in the current year at the start of the irrigation season. The RISD calculation allows for the BLY to adapt to actual conditions by adjustment up or down depending upon the actual water conditions for the irrigation season. The BLY selection criteria were based on three factors 1) climate, 2) available water supply, and 3) irrigation practices, to ensure the BLY is adequate to protect senior water users while providing some level of protection against unnecessary curtailment to the juniors.

BLY selection criteria concerning available water supply include above-average SWC diversions (Figure 2-3**Error! Reference source not found.**) and available SWC supply (Figure 2-4). BLY criteria concerning climate include above-average evapotranspiration (ET) (

Figure 2-5) and Growing Degree Days (GDD) (Figure 2-6), both of which are a function of temperature, and below-average precipitation (Figure 2-7) to ensure the increased diversions in that year(s) were a function of crop water need (CWN) and not other factors. To capture current irrigation practices, identification of a BLY is limited to years subsequent to 1999. Id. at 7096.

These BLY selection criteria have been carried through from First Methodology Order to the Fifth Methodology Order; however, the BLY selected as the benchmark changed in the Third Methodology Order and the Fifth Methodology Order.

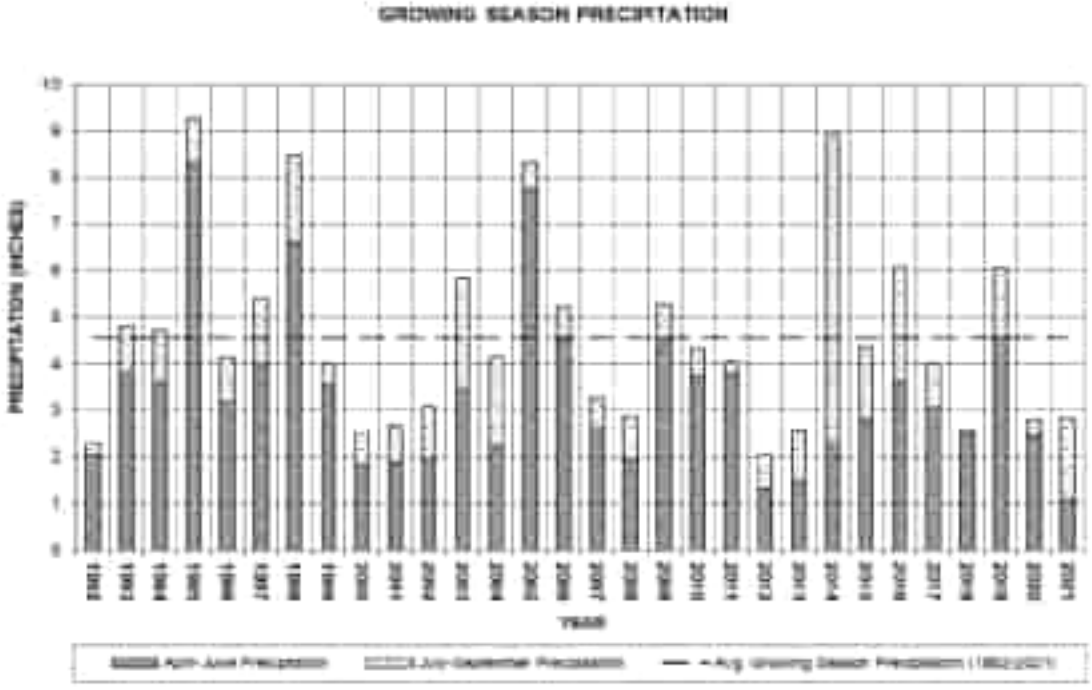

Figure 2-7. *Growing Season Precipitation at National Weather Service's Twin Falls Weather Station 1992– 2021.*

2.1.3.1 BLY First Methodology Order

In the First Methodology Order, paragraphs 27 and 28, found that "from the standpoint of total annual SWC diversion volumes, 2006 is an appropriate BLY with 97% of 2000-2008 total SWC diversion". The Director found that it would also be appropriate to use the values of 2006 and 2008 (06/08) to arrive at an average BLY that more strongly fits selection criteria for all members of the SWC. The First Methodology Order determined 06/08 as the appropriate average of years for the BLY selection. The 06/08 average is 100% of the average for 2000-2008 total SWC entity diversions. Both 2006 and the 06/08 average were determined to be appropriate BLYs.

They are appropriate because they are both so close to the BLY selection criteria averages, it is not necessary to make a determination with bias beyond that. The RISD calculation allows for the BLY to adapt to actual conditions by adjustment up or down depending upon the particular water conditions for the irrigation season. The average for the BLY criteria ensure the BLY is adequate to protect senior water users while providing some level of protection against unnecessary curtailment to the juniors.

2.1.3.2 BLY 2015 Third Amended Order Determination

In the 2015 Third Amended Final Oder the period of record for consideration of the BLY was extended to 2000-2014. It was found that the 06/08 average no longer met the criteria for the BLY.

The 2015 Third Amended Final Order determined 06/08/12 as the appropriate average of years for the BLY which is 101% of the average 2000-2014 total SWC entity diversions. The Director found that 2012 would also met the criteria for the BLY which is 105% of the average 2000-2014 total SWC entity diversions. However, the Director found that because 2012 represents the maximum values for some of the BLY criteria during the period of analysis, 2012 is not an appropriate single-year BLY candidate.

In terms of total SWC diversions an 08/12 average for the BLY would have resulted in 104% of the average 2000-2014 SWC entity diversions. The 06/08/12 average (101% of average) appears to be preferred because it is nearer to the average BLY selection criteria for SWC diversions. Again indicating it is not necessary to make a determination with bias beyond that. The RISD calculation allows for the BLY to adapt to actual conditions by adjustment up or down depending upon the particular water conditions for the irrigation season. The average for the BLY criteria ensure the BLY is adequate to protect senior water users while providing some level of protection against unnecessary curtailment to the juniors.

2.1.3.3 BLY 2023 Fifth Methodology Order

In the 2023 Fifth Methodology Order the period of record for consideration of the BLY was extended to 2000-2021. The Department found that as individual years 2018 and 2020 satisfy all the BLY selection criteria. Additionally, the Department found that 2020 ranks as the second-highest year of total diversions for the SWC and is more than one standard deviation above the average for the years 2000-2021. The 2023 Fifth Methodology Order determined 2018 as the BLY which is 104% of the average 2000-2021 SWC entity diversions.

In terms of total SWC diversions the 06/18 average for the BLY would have resulted in 101% of the 2000-2021 average. Based on previous BLY determinations a selection closer to 100% should have been preferred. The difference between 1% and 4% of bias over the BLY selection criteria for total SWC diversions is 32,000 af and 128,000 af, respectively. For TFCC diversions 2018 as the BLY is 106% of average 2000-2021 where 6% bias is 60,000 af, this is almost the entire shortfall determination of 75,200 af determined in the Final Order Regarding April 2023 Forecast Supply. The 2010 and 2015 Orders make clear that this level of bias is not needed to define an appropriate BLY, 97-101% of the BLY selection criteria is adequate. The RISD calculation allows for the BLY to adapt to actual conditions by adjustment up or down depending upon the particular water conditions for the irrigation season. The average for the BLY criteria ensure the BLY is adequate to protect senior water users while providing some level of protection against unnecessary curtailment to the juniors.

A copy of my January, 2023 comments to the Department in response to their recommendations following the 2022 TWG is included as ATTACHMENT B. Some values in my comment letter were estimated from graphics provided to the TWG and have been corrected based on more accurate data below.

2.1.3.4 Conclusions on BLY selection in Methodology Order

IDWR should consider a percent of average for total SWC diversions and select an average of years closer to that of the 06/08 BLY (100%) and 06/08/12 BLY (101%) selected in 2010 and 2015, respectively. The average of diversion demands for the 2006 and 2018 (06/18) irrigation seasons meet all the BLY criteria (as shown in Table 2-4) and is 101% of total SWC diversion. The BLY of 06/18 has a better technical basis than 2018 as the BLY.

In a hindcast analysis by IDWR staff (ATTACHMENT C), the BLY 2018 causes a huge shift in the type of water year (i.e. wet, average, dry, very dry) where Demand Shortfalls and Shortfall are calculated. The hindcast showed a Demand Shortfall much more frequently in average and even wet years in addition to every dry or very dry year. When you compare the bell-shaped distribution of SWC total diversion demands for the POR 2000-2014 compared to 2000-2021 in Figure 2-8 and Figure 2-9, it is apparent that they are very similar. The average total SWC diversions for the period of record 2000-2014 and 2000-2021 are 3.15 maf and 3.20 maf, respectively. Similarly, the variability in the total SWC diversions for 2000-2014 and 2000-2021, as represented by the standard deviation, are also very close with values of 180,076 af and 178,587 af, respectively. The selection of BLY 2018 translates to a much higher level of bias and is not technically justified given the similarity between mean diversions and the standard deviation for the 2000-2021 POR versus the 2000-2014 POR.

An additional reason for targeting a specific percent of average in line with the average BLY criteria within the POR when establishing a BLY, and for using an average of years (or synthetic diversion volume), is that the process for selection of the BLY otherwise appears arbitrary and subjective. If IDWR staff are presented with multiple years within the POR that fit the criteria for a BLY, and there is no guidance or standard method for selecting a single BLY or average of years, the ultimate selection becomes purely subjective. Using an average of years (or even a synthetic diversion volume) that targets a prescribed percent of average is a more objective and technically defensible process.

Table 2-4. Baseline Year Alternatives and Baseline Year Criteria

BLY Criteria	Avg 2000-2021	BLY Avg 06/18	BLY 2018	BLY 2020
Above Avg SWC diversions	3.20 maf	3.21 maf	3.34 maf	3.54 maf
Above Avg GGD	2526 units	2579 units	2557 units	2597 units
Above Avg ET	1238 mm/d	1265 mm/d	1275 mm/d	1281 mm/d
Blw Avg Precip	4.27 in	3.88 in	2.54 in	2.79 in
Abv Avg SWC Supply	7.45 maf	8.56 maf	9.04 maf	8.22 maf

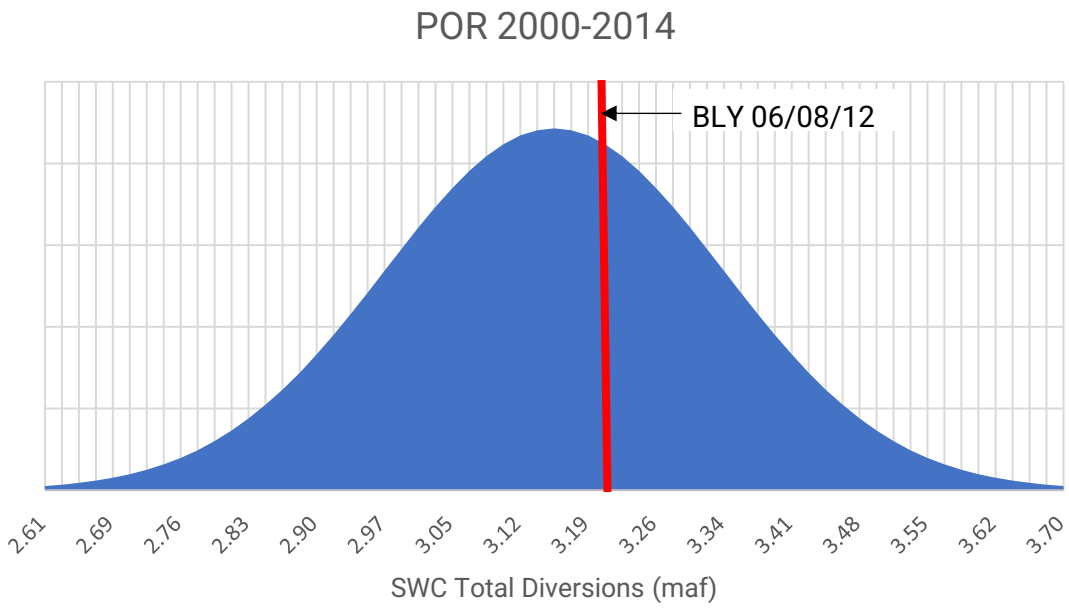

Figure 2-8: Bell Curve of SWC Total Diversion over the POR 2000-2014, the red line shows where the selected BLY 06/08/12 for the 4th Methodology Order falls within the normal distribution.

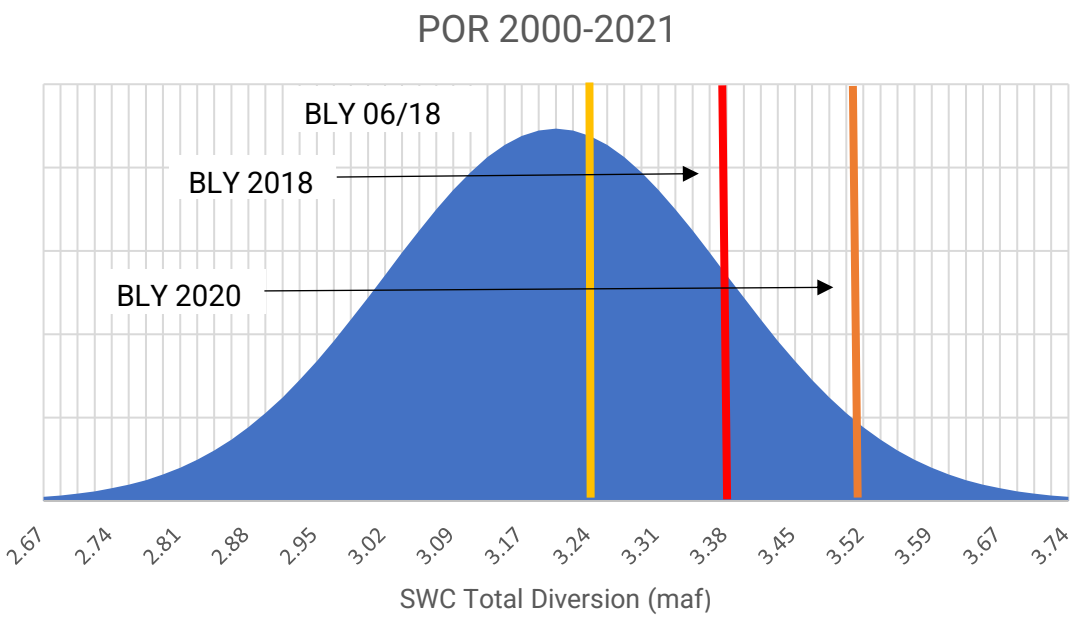

Figure 2-9: Bell Curve of SWC Total Diversion over the POR 2000-2021, the yellow line, red line, and orange line show where the proposed BLY 06/18, 2018 and 2020 falls within the normal distribution, respectively.

Another reason a better alternative would be to use diversion demands for the 06/18 irrigation seasons for the BLY is that there were unique hydrologic circumstances in 2018 that I don't believe represent the typical dry year. The 2017/2018 snowpack was very high and water year forecasts and early season streamflow led to positive water supply forecasts which resulted in a large amount of aquifer recharge in 2018. Department staff acknowledged the technical difficulties in sorting out surface water allocation adjustments like recharge in applying the Methodology Order. In the Department's RISD calculation sheet for "Demand" the table titled "SWC-Monthly Wheeled Water and In-Season Recharge Adjustment Factors (ac-ft)" show the adjustment for recharge and wheeled water. For 2018 there is a note about AFRD2 recharging between 5,000-10,000 af of recharge to MP31 for Magic Valley GWD and the calculation shows only 5,000 af of recharge was accounted for. Additionally IGWA's Settlement Performance Report shows almost 4,000 af of recharge by North Snake GWD through NSCC that is not accounted. This creates a consistent bias of potentially 9,000 af in the application of 2018 as the BLY. This unaccounted for recharge water artificially inflates the 2018 BLY Demand and would directly artificially increase the DS amount calculated in April. The positive water supply outlook in 2018 may have also resulted in less stringent surface water administration and ultimately higher diversions than the crop water need alone would predict.

The BLY criteria concerning precipitation also reveal that 2018 is an extremely low precipitation year. Twin Falls Agrimet station data show the 2018 irrigation season is the only year in the 1992-2021 POR with a zero-precipitation total for July-September and that total irrigation precipitation for 2018 is about one standard deviation below the average. The fact that almost any individual water year will have some unique circumstance is a good reason for continuing to define the BLY based on an average of years as the Methodology Order has previously applied.

2.2 Forecast Supply (FS)

As previously described the shortfall issued in the Methodology Order is the difference between the forecast supply and the forecast demand for each SWC member. The forecast supply has two components: the predicted natural flow supply and the predicted storage allocation for each SWC member. The Department undertakes an April forecast and mid-irrigation season forecast.

2.2.1.1 2015 TWG regarding Forecast Supply

On January 30, 2015 the Director issued an order to staff directing them to convene a TWG to recommend specific changes to the Second Methodology Order. One of the specific recommendations for technical changes was revising the natural flow forecast for Twin Falls Canal Company.

Department staff presented analysis where both single linear regression and multiple linear regression models were considered over the period of record 1990-2013. New multiple linear regression models were recommended to replace existing regression models for TFCC, AFRD2, BID, MID, and NSCC.

In the April forecast for these entities, the final predictor variables selected included the total April through July natural flow in the Snake River near Heise and the total November to March discharge at Box Canyon Springs. Natural flow at Heise is considered a good April predictor of supplied by snowmelt, whereas Box Canyon Springs, was considered by Department staff to be a good indicator for the natural flow supplied by reach gains the in Blackfoot to Milner reach. I disagree with the latter as will be described in a later section.

For the July forecast new forecast models were developed for each SWC member. July natural flow predictors for A&B and AFRD2 are based on Snow Water Equivalent (SWE) Two Oceans Plateau Snotel on July 1. The regressions models for BID, MID, and NSCC include natural flow in Snake River near Heise (April-June), SWE Two Oceans Plateau Snotel on June 15, and March depth to water at well 05S31E27ABA1. I disagree with the use of well 05S31E27ABA1 as will be described in a later section. The predictors in the regression model for TFCC includes Snake River near Heise natural flow (April-June), SWE at Two Oceans Plateau Snotel on June 15, and Spring Creek discharge (January-May).

Table 2-5 shows a summary of all the variables tested in for the linear regression models presented to the TWG in 2015.

2.2.1.2 2022 TWG regarding Forecast Supply

In the 2022 TWG the Department presented December 14, 2022 a presentation on an evaluation of the April and July forecast supply models. This presentation was primarily an overview of how the forecast supply models performed 2014-2022 based on their R^2 values. Unlike the 2015 TWG improving the forecast supply models did not seem to be a priority in 2022 and only a very limited analysis concerning potential model improvement was performed. Table 2-6 shows the list of predictors tested in the 2022 TWG, where the only new predictors were two individual wells and the Sentinel Well index, none of which were found to improve the models for which they were tested.

Table 2-6. Variables Tested in 2022 Multiple Linear Regression Models

Variables in Bold were used in the models		

Department staff did not make a recommendation on updating April and July regression models to improve their predictive power for natural flow supply. However, the presentation to the TWG on natural flow forecasting models did show the TFCC model is degrading in the R^2 value and has decreased from 0.86 in 2014 to 0.72 in 2022. The degradation is significant in that the R^2 values is an expression of the

explanatory power of the forecast model. The technical information presented to the TWG indicates that a revised natural flow method for TFCC should be evaluated and a recommendation for an improved method should be made. There was not sufficient time during the 2022 TWG or prior to the June hearing to perform the necessary analysis as described in section 2.2.3.

2.2.2 Concerns with Current FS Predictor Variables

The next section 2.2.3 outlines my recommendations for how the natural flow models should be developed and could be improved. Aside from those recommendations I have additional concerns about two of the predictors used in the current regression models.

The first is that Box Canyon spring flows are representative of groundwater discharge to the near Blackfoot to Minidoka reach. Box Canyon spring discharges to the Snake River along the Kimberly to King Hill reach of the Snake River. A comparison of reach gains between the near Blackfoot to Minidoka and Kimberly to King Hill reach show that spring discharge between the reaches varies in response to changes in precipitation and precipitation practices. The hydrogeologic controls on spring discharge between these reaches are also different. Aside from the fact that groundwater contributes to both spring reaches there is no logical reason that Box Canyon Springs should be a representative of gains to the near Blackfoot to Minidoka reach gains.

The second concern is related to the use of well 05S31E27ABA1 as a predictor for reach gains. This is a shallow well located near the American Falls Reservoir and located in an area irrigated using surface water. The well shows a rapid response to surface water irrigation practices (Ralston, 2008). The relationship between canal diversions and observed water levels mean that this is not a good representation of groundwater conditions and more likely correlates with near Blackfoot to Minidoka gains as related to surface water supply.

2.2.3 Recommendations on Improving the Natural Flow Models used in the Methodology

The accuracy of predicting April and July natural flow available to SWC entities is dependent on reasonable predictor variables and maintaining high R^2 values over the period of record. The process for natural flow forecast model revision should be standardized in-terms of defining how frequently a thorough re-evaluation of the predictors and models is done (i.e. 3-yrs, 5-yrs, or if R^2 value drops below a threshold). This should include re-evaluating previously tested predictors over the new POR, as well as, casting a new net of total predictors for consideration by the TWG.

The standardized process should include a multicollinearity analysis to screen out variables selected to be predicted that are correlated with one another followed by something like a stepwise regression analysis used to select the most suitable model structure for predicting natural flow.

There was not time for Lynker to perform a proper analysis to demonstrate if there are more accurate models to consider in the natural flow predictions. If time had allowed Lynker would have performed something similar to the following process.

Data collection is the first step in the process. Natural flows are largely controlled by natural hydrologic processes often starting in the sub-alpine and alpine environments. Processes include snow accumulation, evapotranspiration, runoff generation, groundwater flows, and subsurface filling/spilling of subsurface storage. Many data sets exist to describe the hydroclimatic state of water supply and demand in areas that ultimately impact the generation of natural flow.

However, it is difficult to objectively select which predictor variables should be included in a linear regression model. If too few predictor variables are selected, there is a risk of not accounting for an unforeseen control on natural inflows. On the other hand, if too many predictor variables are selected, there is a risk of over-fitting the model, which degrades a model's predictive fidelity. To circumvent this challenge, I propose using stepwise linear regression analysis to construct parsimonious models for the specific SWC entities.

A stepwise linear regression analysis is a regression technique whereby explanatory variables are selected by an automatic procedure that culminates in a parsimonious model that includes only the most important explanatory variables. Provided a list of uncorrelated candidate predictor variables, stepwise linear regression analysis starts with a "maximal" model, which includes all candidate variables. The analysis iteratively removes variables whose omission results in the most statistically insignificant deterioration of the model performance. The Akaike Information Criterion (AIC) is used to objectively quantify the significance variable omission. The variable omission process stops when all predictor variables in the model are statistically significant. Stepwise linear regression analysis is a data-driven approach to construct predictive models and test the utility of additional natural flow predictor variables.

Lynker's technical memorandum included as addendum to IDWR staff recommendations in 2015 laid out an alternative forecast model approach that I continue to think should be further investigated. A better approach would use forecasted flow at Heise or some alternative model that forecasts the physical natural flow supply with subsequent allocation of that physical supply among the rights of the SWC. The technical basis for this suggestion is that water rights administration creates a non-continuous and non-normally distributed dependent variable in the regression analysis. This is likely the reason it is difficult to find a high performing regression model for TFCC.

2.3 Reasonable Carryover

Reasonable Carryover is defined as the difference between the BLY demand and projected typical dry year supply. Reasonable Carryover = BLY Demand – Projected Supply (based on a typical dry year)

The Heise natural flow for the years 2002 and 2004 are well below the long-term average (1992-2021) but not the lowest years on record as shown in Figure 2-4. The percent of average for these years rank very similarly when comparing the period of record for 1990-2014 to the period of record 1990-2022, at 75-79% and 74-78%, respectively. The Fifth Methodology Order like the First Methodology Order, the 3rd Methodology Order, the 4th Methodology Order adopted the average of these years to represent the typical dry year supply.

The Fifth Methodology Order adopts 2018 as the BLY for demand. Like in the DS calculation in April the selection of 2018 as the BLY greatly increases the prediction of carryover need for the SWC (Table 2-7). When Department staff presented the difference in the projected carryover need to the 2022 TWG there was no analysis presented to indicate whether or not this increase in carryover storage was needed based on existing conditions over the time the Methodology Order has been applied. There was not time prior to my writing of this Expert Report to analyze the need for the increased projection of reasonable carryover needs to the SWC.

Table 2-7. Maximum Projected Carryover Need Fourth Methodology Order Compared to the 5th Amended Order

SWC Member	Fourth Methodology Order Reasonable Carryover (af)	5th Amended Order Reasonable Carryover (af)
A&B	18,500	22,696
AFRD2	11,500	93,160
Burley	0	2,495
Milner	4,800	16,072
Minidoka	0	0
NSCC	65,500	113,277
TFCC	25,200	86,834

2.4 Compounding Bias

Each component of the RISD and Forecast Supply calculations in the Methodology Order has a built-in bias in favor of the SWC. These biases are meant to adequately to protect senior water users while providing a level of protection against unnecessary curtailment to juniors. However, these biases have a compounding effect as they propagate through the methodology, resulting in excessive Demand Shortfall predictions that provide essentially no protection against unnecessary curtailment of juniors.

This is apparent from the Department's "Summary of Hindcast SWC Delivery Call Demand Shortfall Calculation 2000-2022" which shows that the Methodology no longer offers any protection against unnecessary curtailment to the juniors. To the contrary, the Fifth Methodology Order leads to the curtailment of every junior groundwater right on the ESPA in most years event though TFCC diversion records (the SWC entity most often short and demanding the largest demand short fall volumes) demonstrate that it is short of water only occasionally. This section will analyze how the compounding biases in the Fifth Methodology Order concerning irrigated acres, BLY, FS, and Reasonable Carryover result in Demand Shortfalls that are unreasonable given the actual water supply and demand conditions over the period of record 2000-2022.

2.4.1 BLY 2018 in April Demand Shortfall Determination

IDWR completed a hindcast analysis 2000-2022 for the April Demand Shortfall volume with 2018 as the BLY, the results of this analysis are shown in column 2 in Table 2-8. The Department provided ESPAM files for May 1 curtailment dates of junior pumping ranging from Oct 1900 to April 1994 that included acres and cfs curtailed. I have used these for column 2-4 in Table 2-8 to estimate the curtailment date most closely associated with the DS calculated in the Department's hindcast. Note that under a transient ESPAM simulation any DS over about 97,700 af results in complete curtailment to the October 1900 date. The analysis shows that for the 23 years in the hindcast 14 years would have resulted in a complete curtailment of all the junior groundwater acres across the ESPA within the area of common groundwater. This means that 60% of the time using 2018 as BLY results in an April DS that demands

complete curtailment of junior groundwater rights and over 940,000 acres curtailed. In contrast column 6 shows TFCC diversion rates in incher per year and only 4 years show that their diversion rates are below the full diversion amount of 5/8" per acre (*emphasized in Bold*). The IDWR hindcast shows only 4 years over the 23-year period where less than 300,000 acres of junior groundwater rights would be curtailed. This demonstrates how extremely conservative the application of 2018 as a BLY in the April DS determination and that the Methodology no longer offers any protection against unnecessary curtailment to the juniors.

Table 2-8. IDWR Hindcast of April Demand Shortfall with BLY 2018 and Lynker Estimated Jr GW Curtailment based on Sukow May 1 Curtailment model files

2.4.2 Erroneous Non-Irrigated Acres for TFCC included in RISD November Actual Demand Shortfall Calculation

As detailed in section 2.1.2 the Department reverted to using out-date irrigated acres for TFCC in their calculation of CWN for RISD starting in 2011. Based on the most current and accurate irrigated acres from IDWR's irrigated dataset I recalculated CWN for the November actual DS and show the difference

in Table 2-9. For the TFCC acres in my analysis I used IDWR's 2011 irrigated lands dataset for years 2011-2016, IDWR's 2017 irrigated lands dataset for years 2017-2020, and IDWR's 2021 NRT METRIC acres for years 2021-2022. This shows that the erroneous use of non-irrigated acres for TFCC results in up to 84,732 af in demand shortfall.

Table 2-9. IDWR Hindcast of November Actual Demand Shortfall based on IDWR RISD with out-dated TFCC acres applied to CWN and Lynker's Corrected RISD with most current TFCC acres

Year	Nov Actual DS (AF)- IDWR Calculation outdated acres	Nov Actual DS (AF)- Lynker Calculation updated acres	Erroneous Shortfall Volume
2011	*0*	*0*	-

2.4.3 Bias in April and July Forecast Supply Models

The forecast supply models predictions are used to predict in April Snake River natural flow volumes for diversion by each SWC entity. To protect the senior SWC water rights each prediction of natural flow is reduced by one standard deviation. Where DS=FS-RISD, this decrease to the FS directly amounts to an equivalent increase in the DS calculated. There was not time prior to my writing of the Expert Report but I would have evaluated this bias in Forecast Supply with respect to the IDWR Hindcast presented in the previous sections.

Table 2-10. April Reduction to Forecast Supply Models for Natural Flow available to SWC entities

SWC Member	April Reduction to FS Prediction (af)
A&B	19,828
AFRD2	32,595
Burley	15,579
Milner	3,221

SWC Member	April Reduction to FS Prediction (af)
Minidoka	17,968
NSCC	54,217
TFCC	47,368

2.4.4 Bias in 2018 BLY for Reasonable Carryover

There was not time prior to my writing of this Expert Report to analyze the need for the increased projection of reasonable carryover needs to the SWC with the use of 2018 as the BLY. However, based on a hindcast analysis presented to the 2022 TWG comparing the Fourth and the Fifth Methodology Orders for Reasonable carryover we can see, like with the April DS determination, the use of 2018 creates a huge difference in how often and the type of water years in which the SWC are determined to have a shortfall to their carryover needs. Figure 2-10 is IDWR's hindcast analysis showing annual carryover volumes for TFCC 1995-2022 under the Fourth Methodology Order (BLY 06/08/12) and the Fifth Methodology Order (BLY 2018). The highlighted carryover volumes indicate years where a shortfall to reasonable carryover would be determined. We can see that under the Fourth Methodology Order only 3 out of the 30 years would have resulted in a carryover shortfall and that these all occurred in very dry or dry years. Under the Fifth Methodology Order 19 out of the 30 years would have resulted in a carryover shortfall and that these occur even in average and above average years.Figure 2-1

			4th Amended Methodology	5th Amended Methodology

2.4.5 Other sources of Bias in the Methodology

There are a few other sources of bias in the Methodology that increase the Demand Shortfall determination. One is that is appears that not all of the recharge water in 2018 diverted through the SWC systems has been removed in the calculation of Demand for 2018. Potentially 9,000 af have not been accounted for and this directly increases the Demand Shortfall calculated every year with 2018 used as the BLY.

The Department does not account for supplemental groundwater use on mixed source lands which represents an additional supply to the SWC.

A critical problem is that the BLY selection criteria method will continue to create additional bias. Under the established BLY criteria, increases in diversion by SWC result in higher BLY demands. There is no examination of acreage or efficiency. It needs to be established that any increase in diversion by SWC entities is related to beneficial use on irrigated lands and not caused by decreases in project efficiencies or diversion of water to meet other needs like hydropower production. As mentioned in

section 2.2.3, and raised in both my 2015 and 2022 TWG comments a better approach would use forecasted flow at Heise or some alternative model that forecasts the physical natural flow supply with subsequent allocation of that physical supply among the rights of the SWC.

3 Simulation of Curtailment of Junior Groundwater Rights Using the ESPAM Model

3.1 Background

The Enhanced Snake Plain Aquifer Model version 2.2 (ESPAM2.2) is the current configuration used for IDWR modeling of the Eastern Snake Plain Aquifer (ESPA). The ESPAM was created with review and input from the Eastern Snake Hydrologic Modeling Committee (ESHMC).

A copy of *Hydrology, Water Right and Groundwater Modeling Evaluation of Rangen Delivery Call* (Brendecke, 2012) is included as Attachment D, section 4.1 provides a detailed description of background on the ESPAM and development.

From the outset of the ESPAM modeling effort, it was recognized that there would be a need for future enhancements to the model as new information and modeling approaches became available. ESPAM version 2.2 is the current version released in 2021. Discussion regarding the scope of future enhancements began shortly after the release with a preliminary release target date for the next model in 2026. With each model version release potential objectives to advance the model are made with ESHMC input, not all of which are accomplished because there is either insufficient time, insufficient data or are generally considered a low priority.

3.2 Model Structure

ESPAM is developed in MODFLOW, a groundwater modeling environment developed by the U.S. Geological Survey (McDonald and Harbaugh, 1988; 2000). A copy of *Hydrology, Water Right and Groundwater Modeling Evaluation of Rangen Delivery Call* (Brendecke, 2012) is included as Attachment D, section 4.2 provides a detailed description of the ESPAM model structure.

ESPAM2.2 was converted to MODFLOW-USG a code developed by the USGS (Panday, et al, 2013). While the MODFLOW-USG code supports a wide variety of structured and unstructured grid types and includes the ability to have multiples layers across the whole domain or in select areas of the model. ESPAM2.2 uses the same structured grid as ESPAM2.1. ESPAM2.2 is represented as a single layer with uniform thickness. In the ESPAM the aquifer is represented within a defined model boundary by individual model cells at a one-mile by one-mile uniform grid. The MODFLOW code solves the equations of flow between these cells to determine aquifer responses to changes in inputs or outputs. MODFLOW has the capability to represent anisotropy (where flow occurs in preferential directions), but this feature has not been used in any versions of the ESPAM.

Key differences between ESPAM2.2 and its predecessors include a longer study period (2008-2018), the adoption of METRIC data to estimate ET, structural changes including American Falls Reservoir area springs and spring fed river reaches and the addition of the Portneuf River. Additional work also included adding the Menan gage to separate the Heise to Shelley river reach, additional calibration targets for river reaches, finer spatial resolution for aquifer recharge from surface water irrigation

entities, calibration methods, and structural changes to drain boundaries of the Kimberly to King Hill reach. ESPAM2.2, like its predecessor ESPAM2.1 (released 2013) uses monthly stress periods.

3.3 Model Calibration Process

The typical development of a groundwater flow model involves creating a conceptual model and water budget for the system to be represented. These form the basis for the model structure and model inputs. After formulation of the model the next step in development is calibration. Calibration is a form of "history matching" wherein initial values of model parameters (such as transmissivity) are adjusted to achieve a better correspondence between historical targets (e.g., measured water levels and spring and river flows) and model-predictions.

A copy of *Hydrology, Water Right and Groundwater Modeling Evaluation of Rangen Delivery Call* (Brendecke, 2012) is included as Attachment D, section 4.4 provides a detailed description of the ESPAM model calibration process.

The software program used to calibrate all versions of the ESPAM has been the model-independent Parameter ESTimation program (PEST) developed by John Doherty (Watermark, 2005). While the calibration of models with large numbers of parameters (such as ESPAM2.2) allows consideration of more factors affecting aquifer conditions, it increases the risk that any given PEST solution (i.e., an "optimal" set of parameter values) is not unique (Watermark, 2005). This means that there may be many other combinations of parameter values could produce a similarly minimized value of overall model error. This non-uniqueness creates one dimension of overall model uncertainty, which is discussed in more detail in a later section.

The parameters that PEST was allowed to adjust in ESPAM2.2 included aquifer parameters such as transmissivity and specific yield. In addition, PEST was allowed to manipulate a number of terms in the aquifer water budget where precise values could not be known (like recharge on non-irrigated lands and tributary valley underflow).

3.4 Model Uncertainty

Any groundwater model is necessarily a simplification from the real world. The simplifying assumptions must be made to model complex natural systems. ESPAM2.2 inherently has limitations and uncertainty. As noted by IDWR in the 2021 ESPAM2.2 Model Calibration report, water budget parameters are adjusted during calibration simultaneously with the aquifer properties transmissivity and specific yield, resulting in a non-unique solution. The calibration results for these aquifer parameters are affected by assumptions regarding the uncertainty of water budget parameters. The ramifications of this are discussed in more detail in a later section.

The courts have recognized ESPAM as the best science available. Accepting that does mean that the inherent uncertainty in the model should be ignored in its application. As IDWR notes in their 2021 report of ESPAM2.2 model predicted uncertainty:

> Acknowledgement and a general understanding of the uncertainty associated with predictions made by the ESPAM2.2 is important to guide the use of the model as a tool for water management and administration.

3.4.1 Overview of Model Uncertainty

Model uncertainty has several dimensions, and these have been described in various submittals to the ESHMC (e.g., Brendecke, 2009a,b; 2012). Essentially, the principal dimensions of model uncertainty are those associated with model conceptualization, with model input and with model calibration. While all of these dimensions are important, conceptual uncertainty is fundamental. No amount of data improvement, re-sampling or recalibration can correct errors stemming from incorrect (or simply incomplete) model conceptualization (Bredehoeft, 2005).

A copy of *Hydrology, Water Right and Groundwater Modeling Evaluation of Rangen Delivery Call* (Brendecke, 2012) is included as Attachment D, section 4.6 provides a detailed description of ESPAM model uncertainty.

3.4.2 Examples of ESPAM2.2 Conceptual Model Limitations Leading to Uncertainty in near Blackfoot to Minidoka Reach Gain Prediction

The predictive uncertainty analysis of ESPAM2.2 carried out by the IDWR explores only a limited aspect of model uncertainty and does not quantify overall model uncertainty.

Fundamental to overall model uncertainty is the uncertainty associated with the conceptual model reflected in ESPAM2.2. The predictive uncertainty analysis relies on a single conceptual model and does not explore uncertainty that arises from improper conceptualization of local geology and hydrologic conditions that influence discharge to the near Blackfoot to Minidoka Reach.

The ESPAM2.2 configuration with a single layer model representation is not adequate to represent the hydrogeologic controls on groundwater discharge to the near Blackfoot to Minidoka Reach. Several hydrogeologic studies were summarized by Ralston Hydrologic Services (“Ralston”) in their report *Hydrogeologic Analysis of the Near Blackfoot to Neeley Reach of the Snake River* prepared for IDWR in 2008 (ATTACHMENT E). This report characterizes the hydrogeological conceptual model for the near Blackfoot to Neeley reach of the Snake River.

The Quaternary basalt near the center of the Snake River plain is generally considered to host a single unconfined aquifer where average hydraulic conductivity of the basalt is extremely high. The inter-fingering of Quaternary basalt flows with fine-grained sediments (i.e. Raft River Formation and American Falls Lake Beds) in the vicinity of the American Falls Reservoir results in an aquifer system composed of individual aquifers and confining units (aquitards). The presences of fine-grained sediments around American Falls Reservoir likely result in lower transmissivity compared to the aquifer to northwest where these materials are absent. Northeast of the reservoir a shallow gravel unit roughly parallel to the Snake River is present.

The presence of the fine-grained sediments (Raft River Formation and American Falls Lake Beds) likely act as restriction for southwestward ground-water flow in both the basalt and the gravel along the Snake River. This results in upward hydraulic gradients and groundwater discharge in the form of springs and river gains. The inter-fingering of the basalt and fine-grained sediments in the vicinity of the American Falls Reservoir and the distribution of the gravel deposits to the northeast is illustrated in Figure 3-1 and Figure 3-2.

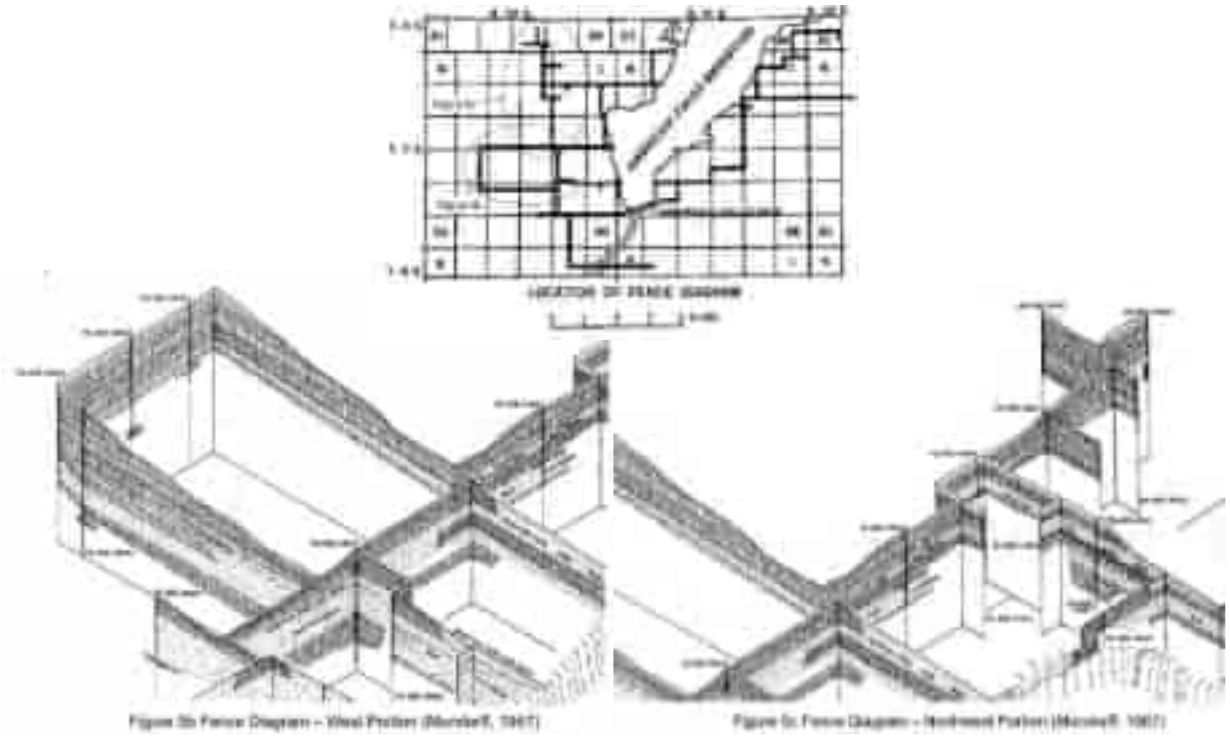

Figure 3-1: Excepts from Ralston (2008) Figures 5a,b,c showing Fence Diagrams of subsurface geology around the American Falls Reservoir from Mundorff (1967).

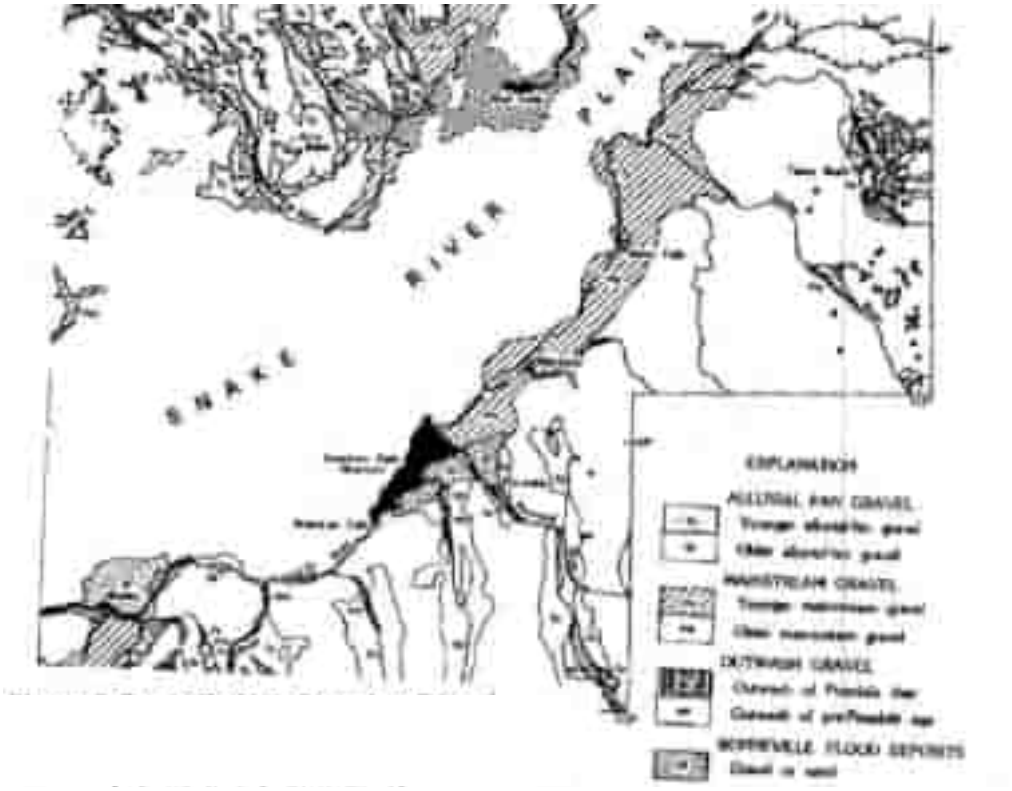

Figure 3-2: Except from Ralston (2008) Figure 8 of geologic map showing the gravel deposits along the Snake River by Piece and Scott, 1982).

These features mean that groundwater discharge to the near Blackfoot to Neeley reach is a function of the combination of water from shallow aquifers that are hydraulically connected to the basalt system of the main ESPA and vertical fluxes from the deeper aquifer units that are hydraulically connected. The magnitude of upward groundwater flow depends on the hydraulic gradient and the vertical hydraulic conductivity of the basalts and sediments in the areas. A single layer does not allow for the evaluation of vertical hydraulic conductivity or vertical flow within the aquifer or discharge characteristics of the individual springs or stream-gains areas.

The ESPAM2.2 transmissivity distribution (Figure 3-3) does not fit the know hydrogeologic characteristics of the region. Ralston (2008) describes how groundwater discharges to the Snake River in the near Blackfoot to Neeley reach because the transmissivity around and southwest of American Falls Reservoir is low compared to the upstream aquifer. The model should show high transmissivity representative of basalt and gravel dominated system north and northeast of American Falls Reservoir transitioning into low transmissivity representative fined-grained, sedimentary dominated system under the reservoir and to the southwest. Conceptual and calibration considerations should be made in the advancement of ESPAM2.2 to achieve a transmissivity array that better fits the hydrogeologic framework. In my recommendations for future improvements following the release of ESPAM2.2 I recommended an investigation to better understand groundwater gradients near the American Falls Reservoir reach.

3.4.3 Examples of ESPAM Input Parameters Leading to Uncertainty

As previously discussed, for ESPAM2.2 the water budget parameters like the ET rate for consumptive use by groundwater and components representing natural recharge to the groundwater system are adjusted during calibration simultaneously with the aquifer properties like transmissivity (T) and the aquifer storage specific yield (Sy), resulting in a non-unique solution. The calibration results for the aquifer parameters (T, Sy) are affected by assumptions regarding the uncertainty of water budget parameters.

ESPAM2.2 was adopted by the ESHMC following a vote in a September 9th, 2020 committee meeting. The Department had presented another version of the model for consideration to adopt as ESPAM2.2 in January 2020[2]. At the January, 2020 ESHMC meeting I presented an “impact analysis” of the proposed ESPAM2.2 version compared to ESPAM2.1 after my review of the model showed significant differences in model predictions, particularly for changes in water levels from simulated aquifer stresses. At the conclusion of the January ESHMC meeting it was decided that the validation run years (2015-2018) would be included in the ESPAM2.2 calibration, as well as, new irrigated lands maps (2015) to further evaluate the calibration results. At the September 2020 meeting IDWR again proposed a final ESPAM2.2 calibration with changes including updated water budget data through 2018.

3.4.3.1 ESPAM Aquifer Parameter Uncertainty ESPAM1.1 to ESPAM2.2

Figure 3-3 and Figure 3-4 below show the evolution of aquifer parameter distributions of transmissivity and specific yield, respectively, between ESPAM1.1, ESPAM2.1, ESPAM2.2 (proposed in January) and ESPAM2.2 (proposed in September and accepted as final).

[2]Based on calibration & modeling information provided to ESHMC September, 2019 and November, 2019

Compared to ESPAM2.1 the calibration results show a significant ESPA wide change of increased aquifer storage (Sy), as well as, generally lower aquifer transmissivity (T) that result in changes to pumping response functions and predicted stream depletion timing throughout the model domain.

Figure 3-5 shows the difference in simulated reach gains between ESPAM2.1 and ESPAM2.2 for the Departments 1/1/1961 curtailment scenario (Sukow, 2021). The ESPAM2.2 results in increased reach gains above Milner in response to curtailment. The near Blackfoot to Neeley reach shows one of the biggest increases overall with reach gains of 760 cfs and 931 cfs for curtailment of junior groundwater pumping to 1961priority date with ESPAM2.1 and ESPAM2.2, respectively. The percent difference is about 20%. The change in the steady state response function to the near Blackfoot to Minidoka reach between ESPAM2.1 and ESPAM2.2 is shown in Figure 3-6.

The Sentinel Wells which make-up the IGWA-SWC index for the 2015 Settlement Agreement were selected based on achieving the highest correlation (R^2~.63)[3] with the near Blackfoot to Minidoka reach gains. The aquifer level rise across the Sentinel Wells in ESPAM2.2 is about 50-60% of what was predicted with ESPAM2.1.

This changes between ESPAM2.1 and ESPAM2.2 illustrate the difference in predicted water level rise across the ESPA and modeled reach gains to the near Blackfoot to Minidoka from changes in aquifer properties transmissivity (T) and specific yield (Sy).

[3] Technique for Calculating Groundwater Level Index and Determining Compliance with Settlement Agreement Targets, August 8, 2016.

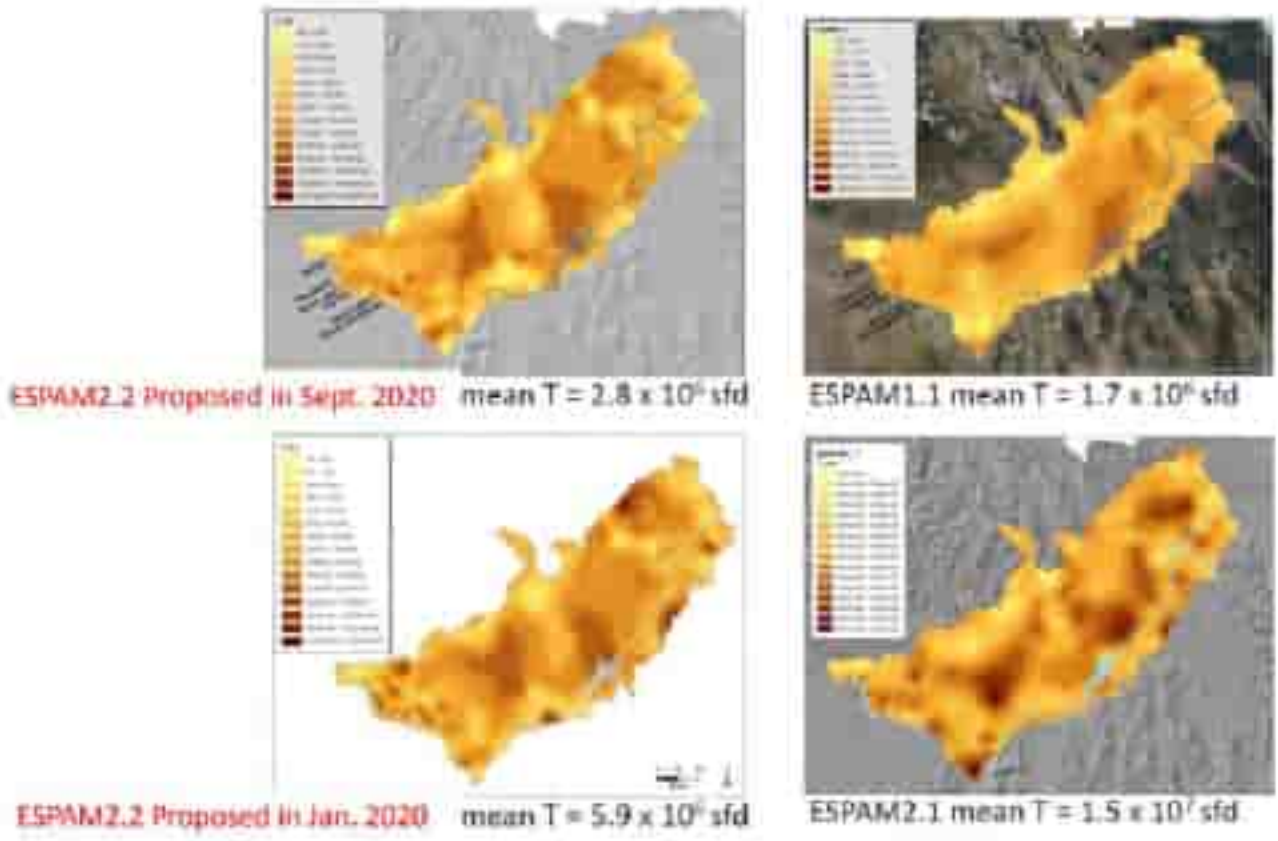

Figure 3-3: Transmissivity (T) changes ESPAM1.1 (UR), ESPAM2.1 (LR), ESPAM2.2 (proposed January 2020) (LL), ESPAM2.2 (proposed September 2020 (UL). Darker oranges indicate higher values, lighter oranges indicate lower values.

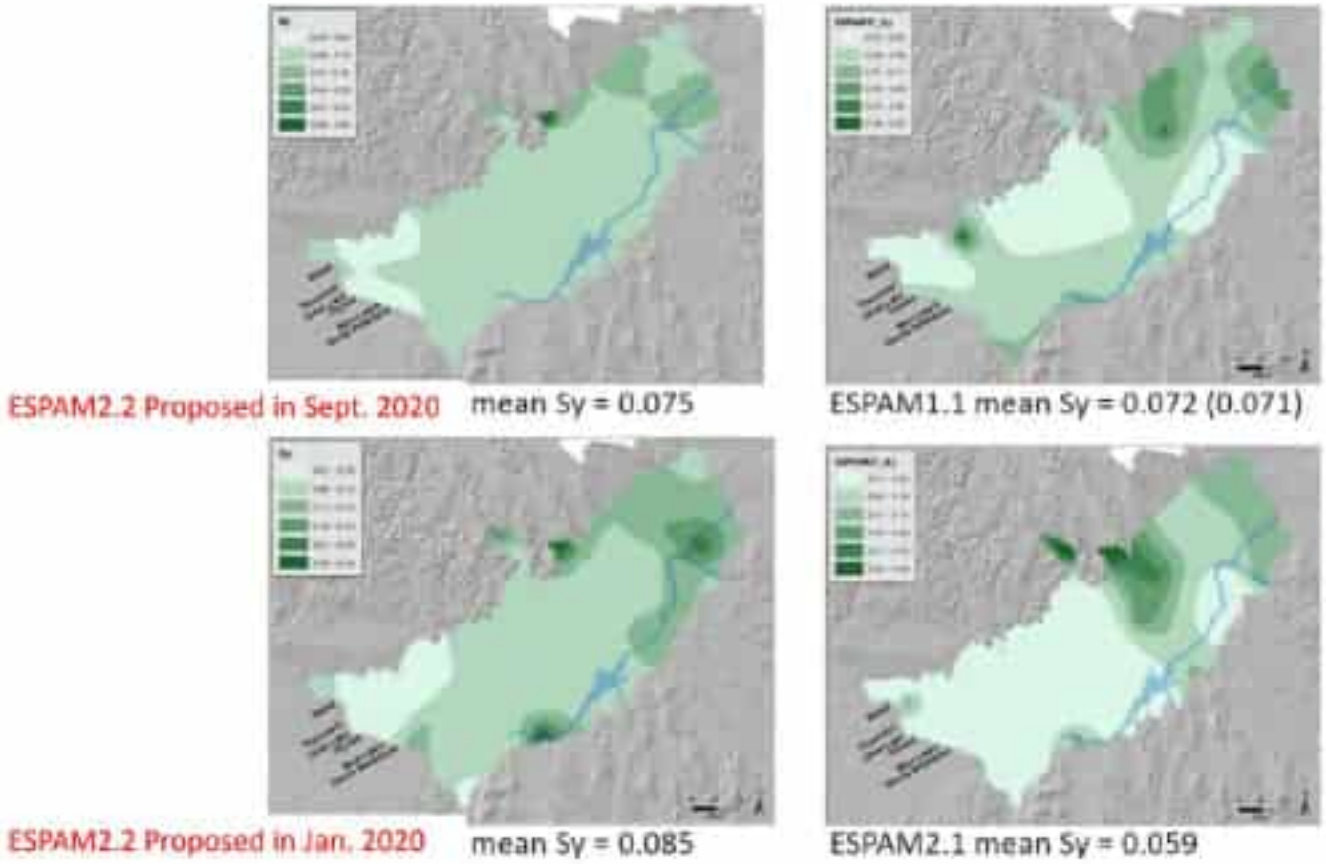

Figure 3-4: Specific Yield (Sy) changes ESPAM1.1 (UR), ESPAM2.1 (LR), ESPAM2.2 January (LL), September (UL). Darker greens indicate higher values, lighter greens indicate lower values.

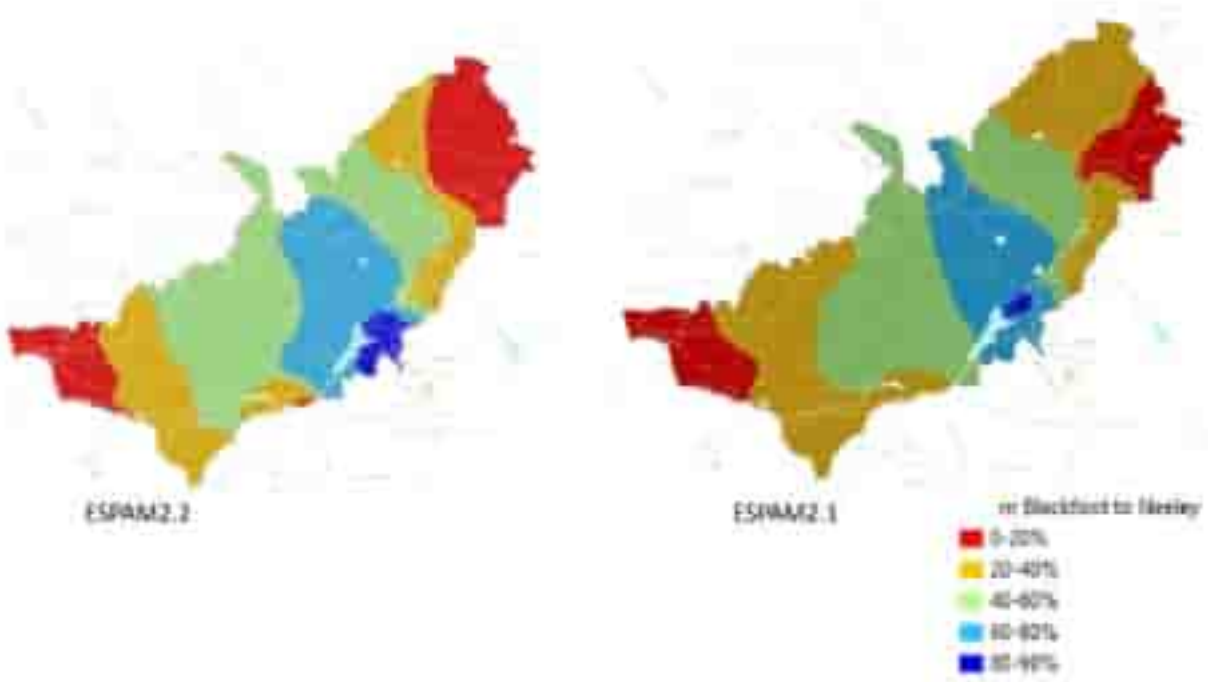

Figure 3-6: Changes in steady state response function for near Blackfoot to Minidoka river reach gains for ESPAM2.1(right) and ESPAM 2.2 (left).

3.4.3.2 ESPAM Water Budget Components Uncertainty ESPAM2.2

In ESPAM2.2 the aquifer parameters (T, Sy) and the water budget components (natural recharge, ET for consumptive groundwater use) are both adjusted during calibration. This means uncertainty in one of these components leads to uncertainty in the other. In the presentation of my impact analysis to ESHMC January, 2020 I was concerned about the change seen to aquifer storage following my review of the proposed ESPAM2.2 calibration, as shown in Figure 3-4. I did not believe the ESPA wide change in storage parameters could be explained by the localized structural model improvements and extending the period of record for the water budget components in ESPAM2.2. Because intermediary calibration results had not been presented to ESHMC it was impossible to parse out what change was leading to the new aquifer parameter distributions. I made the recommendation to the Department that ESPAM be calibrated a step-wise approach so we could understand the result of each major model change, as well as, sensitivity testing for 1) changes in the calibration approach and 2) the METRIC processing method used to calculate ET for groundwater consumptive use

It was my belief that only either a change in the calibration method (e.g. pilot point distribution, regularization, or parameter weighting) or the METRIC processing for the ET rate for groundwater consumption (one of the biggest water budget components) could be responsible for such wide spread changes in the aquifer parameter values between ESPAM2.1 and ESPAM2.2.

My only concern around changes to the calibration method was that a simple change in calibration procedures should not significantly change the entire model results or if it did we should understand why.

I had two main areas of concern regarding the METRIC processing for ESPAM inputs. First, I was part of the METRIC TWG in 2015 that developed the processing methods for the METRIC data. The Department's processing of METRIC data for ESPAM included using a 90-meter buffer around the irrigated areas that ultimately increased the rate of ET used when applied to the irrigated lands acreage. There did not appear to be a well-founded reason around the specific choice of 90-m. That is why I recommended a sensitivity test to explore the impacts of this choice on the model calibration. The second, was that when I reviewed the calibration analysis for ESPAM2.2 it was obvious that the calibration tool PEST was adjusting parameters in ways that seemed to be compensating for the rate of groundwater ET being too high. For example, the significant increase in aquifer storage (Sy). Another example is the PEST adjustments to sources of natural recharge across the ESPA. The pre- and post-calibration time-series for water budget components that make up natural recharge are shown in Figure 3-7. It is evident that post-calibration results are much higher, indicating that to match model results to observed values the calibration tool PEST is trying to get more water into the ESPA. Again possibly compensating for groundwater ET rates being too high. This is particularly evident when comparing the pre- and post-calibration results for tributary underflow and recharge on non-irrigated lands.

Figure 3-7: Annual volume of net aquifer recharge, tributary underflow and recharge on non-irrigated lands water years 1981 through 2018

When the Department ultimately accepted the September 2020 ESPAM2.2 calibration as final they sent notice to the ESHMC members asking for suggestions for areas of improvement for the next version of ESPAM. Again, I recommended (along with several other issues), that a sensitivity analysis for the METRIC ET processing be performed. This was voted as a priority by the rest of the ESHMC. January 2023 the Department gave a presentation to ESHMC on METRIC where initial findings were that when the Department processing of METRIC for ESPAM was compared to both to a field-scale investigation using groundwater diversion data and two openly available sources of METRIC ET (ssebop and eemetric) the Department's method was consistently too high. The Department consulted with METRIC experts and concluded that it was not appropriate to apply a 90-m outer buffer and that best practices would apply an inward buffer to ensure that the most accurate METRIC pixel value was applied for to the irrigated lands dataset acres. These processing alternatives were presented to ESHMC May 2023 along with the Department's preliminary recalibration of ESPAM2.2 using the no buffer processing method alternative. Based on the preliminary recalibration of ESPAM (unbuffET_mile_003) the distribution for storage (Sy) and Transmissivity (T) compared to ESPAM2.2 are shown in Figure 3-8. This shows that model storage on average is less than ESPAM2.2, as well as, transmissivity with the alternative METRIC processing.

As previously discussed, the uncertainty in the water budget components directly results in the uncertainty of the aquifer parameters because errors in the water budget can be compensated by changes in aquifer properties to ensure the best model fit for observed versus simulated results like reach gains. The comparison of water budget components pre-and post-calibration based on the preliminary recalibration of ESPAM2.2 using alternative METRIC processing are shown in Figure 3-9.

There are several water budget components where the difference between the METRIC processing method is evident. Tributary basin under flow and recharge on non-irrigated lands are both about 300K af lower compared to ESPAM2.2 and we see that these components need to be adjusted much less pre- and post-calibration. Recharge on surface water irrigated lands is increased by about 300k af. The consumptive irrigation requirement (CIR) on groundwater irrigated lands is about 500K af lower. These differences demonstrate the uncertainty in the water budget components of the ESPAM model including those directly related to curtailment of junior groundwater rights. These uncertainties in the water budget inevitably result in uncertainty in the aquifer parameters that control the timing and magnitude of near Blackfoot to Minidoka reach gains in the ESPAM2.2 simulation of curtailment of junior groundwater rights.

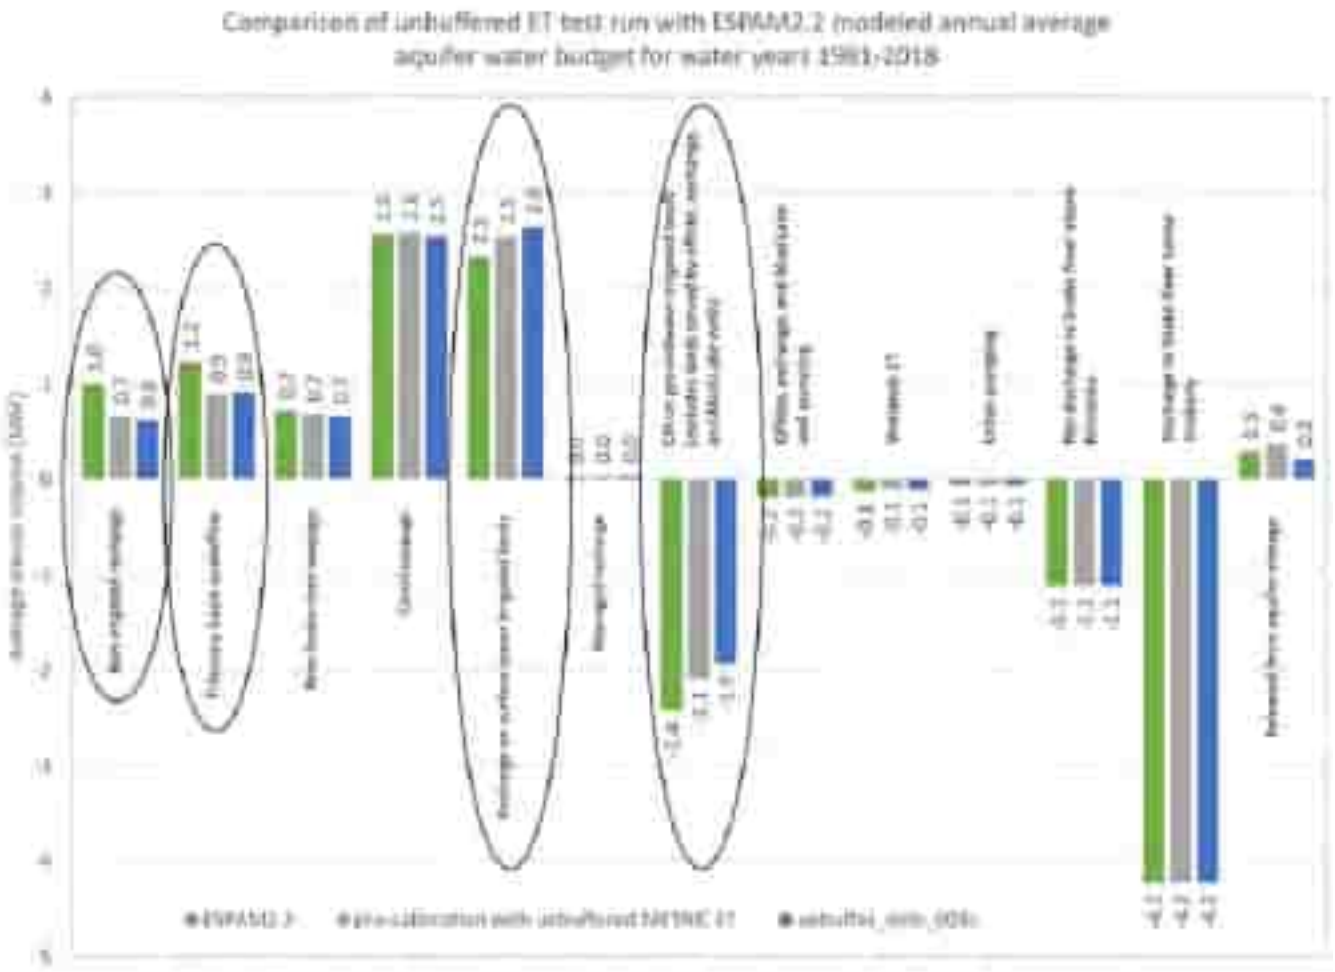

Figure 3-9: Comparison water budget components pre-and post-calibration based on preliminary recalibration of ESPAM2.2 using alternative METRIC processing (model version "unbuffET_mile_003c")

3.4.4 Conclusions on Model Uncertainty and the Application of ESPAM for Simulating Curtailment of Junior Groundwater Right for the Methodology

ESPAM2.2 is used in the Methodology to find the curtailment date of junior groundwater pumping that amounts to reach gains to the near Blackfoot to Minidoka reach of the Snake River equivalent to the Demand Shortfall calculated under the Methodology As-Applied Order. The Fifth Methodology Order transitions from a steady state to a transient ESPAM simulation to determine the amount of junior groundwater rights that must be curtailed for an in-season equivalent reach gain response to the Demand Shortfall. The April 2023 As-Applied Order determined a December 30, 1953 curtailment date and shows total proportionate share for all members of IGWA as 63,645 af.

IGWA requested that IDWR break the obligation down within IGWA by ground water district. As a response, IDWR provided the first two columns shown in Table 3-1. IGWA districts were interested in knowing the transient response given the curtailment scenario under the Fifth Methodology Order is now run using a transient ESPAM simulation. Jaxon Higgs provided the analysis but will be out of the country during the hearing and unable to testify. I reviewed the analysis and can testify to results

shown in Table 3-1. The IDWR MODFLOW wel input file was split by district based on their geographic boundaries as shown in Figure 3-10 and run with ESPAM2.2 to calculate individual district curtailment impact to the Near Blackfoot to Neeley reaches (SWC reaches) from May-September.

Table 3-1. Results of Jaxon Higgs Analysis on IGWA's Proportionate Share Related to Reach Gain Benefits and Acres Curtailed for the April 2023 As-Applied Order

GWD	IGWA % of IGWA's proportionate share	IDWR Portion of April 2023 predicted demand shortfall		Transient May - Sept Impact[1]	May - Sept Curtailed Volume[2]	Ratio of Curtailed to Benefit	Pr. to 12/1953[3]	District Total	% of Acres Curtailed	Baseline Volume[4]

Grand Total				**74,720.8**	**1,597,639**	**21:1**				

1. Impact broken down by geographic boundary. Some non-members are included in each district. For example, the A&B usage is included in Magic Valley and North Snake GWDs. See accompanying map. Acre-ft rounded to 2 decimal places.
2. Total volume split geographically as described in note 1 from IDWR model input files from Jr12301953 run. Some slight conversion and rounding errors.
3. Acres provided by each district except Carey, Henry's Fork, and Madison. Based on breakdown of combined acres to provide effective acres per water right. 4. Baseline volume taken from 2022 Settlement Report submitted by IGWA to IDWR and the Surface Water Coalition. Represents average usage from 2010-2014.

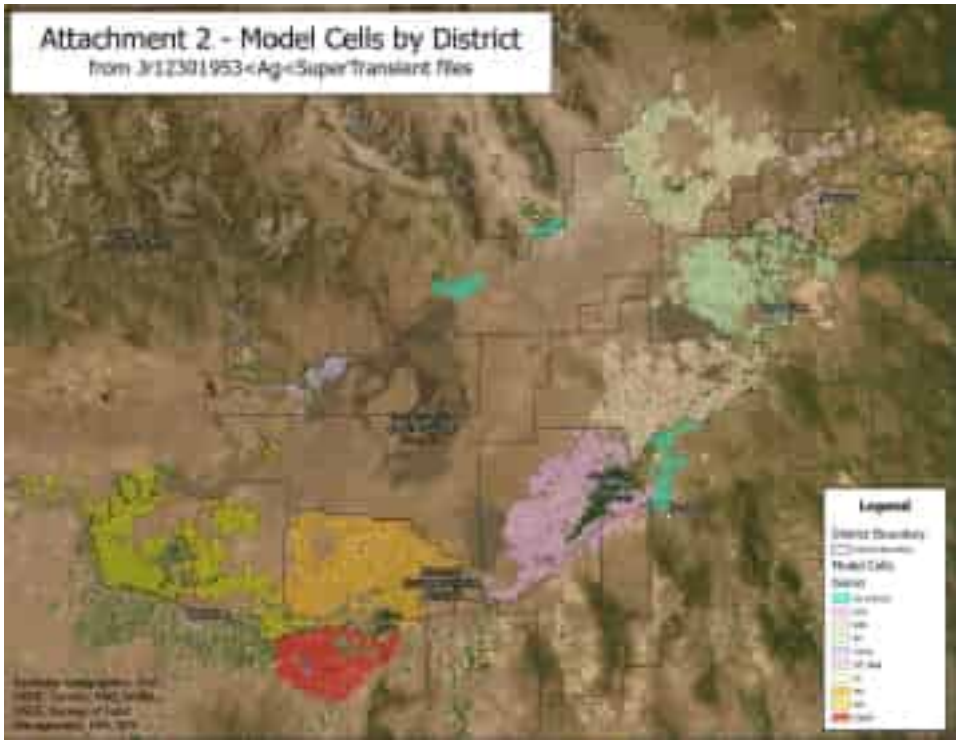

Figure 3-10: Distribution of junior groundwater pumping curtailed under 12/31/1963 priority date broken out by Groundwater District (Jaxon Higgs)

The results of Higgs' analysis show that the benefit to the SWC reach compared to the junior groundwater volume curtailed varies greatly by groundwater district. This is a result of their distance and hydrologic connection to the reach.

ESPAM2.2 is not sufficiently detailed in its representation of hydrogeologic conditions at the near Blackfoot to Minidoka reach to be used to accurately predict change in discharge due to curtailment of junior groundwater rights on the ESPA. Using ESPAM2.2 the number of junior groundwater acres that would be curtailed that do not have significant in-season benefits to the near Blackfoot to Minidoka reach is between 300,000-400,000 acres. The water from these rights will accrue to other connected river reaches, springs, without benefit to the SWC, or in years when the water is not needed. The wide-spread curtailment will, by any reasonable standard, result in waste of the resource.

ESPAM2.2 is highly simplified in the conceptual model in the near Blackfoot to Minidoka reach ignoring several critical hydrogeologic features that would make significant differences in predicted benefits of curtailment. The ESPAM water budget components related to junior groundwater use and the aquifer properties are uncertain and the variability in these components make significant differences in predicting benefits of curtailment. That ESPAM2.2 can fairly closely match observed discharge to the river is not proof that it represents the hydrogeological reality to sufficiently predict future behavior especially under aquifer wide water use conditions (e.g., curtailment of junior groundwater pumping).

If the Director uses ESPAM2.2 to quantify the benefits to the near Blackfoot to Minidoka reach from curtailment of junior groundwater uses, this quantification should reflect the substantial uncertainty in that model prediction and a trimline respective of the level of model uncertainty should be applied.

4 Summary of Conclusions

Irrigated Acreage

1. Evidence presented in prior hearings show a trend of decreasing irrigated acreage, particularly within TFCC due to urbanization of the City of Twin Falls and surrounding area. Beneficial use does not occur on acres that have been hardened or are otherwise not irrigated.
2. Every technical analysis of irrigated acres within TFCC consistently shows that TFCC is irrigating approximately 15,000 acres less than the 194,732 acre figure that TFCC reports to IDWR as being irrigated.
3. The Department is not using the best science available to determine irrigated acres in the Fifth Methodology Order, relying instead on outdated acreage figures provided by SWC entities.
4. The Department should implement a review process in Step 1 of the Methodology Order that compares the irrigated acreage figures reported by SWC entities with the irrigated acreage data in the most recent Irrigated Lands data set and/or using METRIC data. The Department should also account for supplemental groundwater use as a source of supply to SWC entities.

Baseline Year

5. The BLY demand for 2018 includes recharge water that has not been accounted for.
6. The BLY 2018 has total precipitation far below the average for the period of record.
7. Hindcast analysis show the BLY 2018 frequently predicts Demand Shortfalls for TFCC in years when TFCC is not actually short of water.

8. The BLY 2018 significantly increases the reasonable carryover demand shortfall in average and above average water supply years. No technical justification for this has been demonstrated.
9. In selecting the BLY, IDWR should consider a percent of average for SWC diversions within range of 97-101% and select an average of years closer to that of the BLY 06/08 (100%) and BLY 06/08/12 (101%) utilized in the First Methodology Order and Fourth Methodology Orders, respectively.
10. The average diversion demands for the 2006 and 2018 (06/18) irrigation seasons meet all the BLY criteria and is 101% of total SWC diversion. This 06/18 average (or a synthetic diversion volume) should be used as the BLY as it represents 101% of average total SWC diversion.
11. A critical problem is that the BLY selection criteria utilized to date create excessive bias in favor of senior water users. Under the current BLY criteria, increases in diversion by SWC result in higher BLY demands, incentivizing SWC entities to divert more water than is needed to grow crops, and disincentivizing water conveyance efficiency. A new BLY method should be developed that accounts for non-irrigated acres , ensures that any increase in diversion by SWC entities is related to beneficial use on irrigated lands and is not caused by decreases in project efficiencies or diversion of water to meet other needs like hydropower production, and incentivizes water conveyance efficiency.

Forecast Supply

12. The forecast supply model for TFCC is degrading in its explanatory power based on regression data, resulting in inaccurate predictions for natural flow to TFCC
13. Box Canyon Springs discharge is not representative of discharge to the near Blackfoot to Neeley Reach. This should not be used in the April Forecast Supply Models.
14. Well 05S31E27ABA1 is not representative of groundwater conditions in the vicinity of the near Blackfoot to Neeley Reach. This should not be used in the July Forecast Supply Models.
15. A better alternative to the FS models could use forecasted flow at Heise or other model that forecasts the physical natural flow supply with subsequent allocation of that physical supply among the rights of the SWC.

Model Uncertainty

16. . ESPAM2.2 is, like all models, a simplified representation of reality, and its predictions contain a degree of uncertainty.
17. ESPAM is a single-layer model which assumes the ESPA is homogenous and isotropic. By contrast, the hydrogeology in the vicinity of the near Blackfoot to Minidoka reach suggests the aquifer system is multi-layered with vertical gradients that result in discharge to the reach that require a multi-layered modeled with anisotropic properties. ESPAM's current inability to represent multiple hydrogeologic layers may result in substantial misrepresentation of flow conditions in some parts of the aquifer.
18. Fundamental to overall model uncertainty is the uncertainty associated with the conceptual model reflected in ESPAM2.2. The predictive uncertainty analysis relies on a single conceptual model and does not explore the uncertainty that arises from improper conceptualization of local geologic and hydraulic conditions of the near Blackfoot to Minidoka reach.
19. The large number of parameters adjusted during calibration of ESPAM2.2 increases the likelihood that the model in not unique.

20. ESPAM2.2 has demonstrable uncertainty in the aquifer parameters for transmissivity and specific yield which will impact the timing and magnitude of reach gains to the near Blackfoot to Minidoka reach simulated under the curtailment of junior groundwater rights.
21. ESPAM2.2 has demonstrable uncertainty in the water budget components, particularly consumptive use of groundwater, which impact the timing and magnitude of reach gains to the near Blackfoot to Minidoka reach simulated under the curtailment of junior groundwater rights.
22. The predictive uncertainty analysis of ESPAM2.2 carried out by IDWR explores only a limited aspect of model uncertainty and does not quantify overall model uncertainty.
23. That ESPAM2.2 can fairly closely mimic the observed past behavior of the near Blackfoot to Minidoka reach is not proof that it accurately predicts the effect of curtailment of junior groundwater pumping.
24. ESPAM2.2 is not sufficiently detailed in either its general formulation or its representation of hydrogeologic conditions in the vicinity of the near Blackfoot to Minidoka reach to be used reliably to predict changes in reach gains due to curtailment of junior groundwater rights on the ESPA.
25. ESPAM2.2 represents the surrounding geology to the near Blackfoot to Minidoka reach in highly simplified form, omitting several key features and that would make significant differences in predicted benefits of curtailment.

Transient Application of ESPAM

26. Under a transient simulation with ESPAM2.2, the benefit to the near Blackfoot to Minidoka reach in-season compared to the junior groundwater volume curtailed varies greatly by groundwater district. This is a result of their distance and hydrologic connection to the reach.
27. Using ESPAM2.2 the number of junior groundwater acres that would be curtailed that do not have significant in-season benefits to the near Blackfoot to Minidoka reach is between 300,000-400,000 acres. The water from these rights will accrue to other connected river reaches, springs, without benefit to the SWC, or in years when the water is not needed. The wide-spread curtailment will, by any reasonable standard, result in waste of the resource.

Subject: Recommended revisions to the Surface Water Coalition Methodology

Introduction

On January 30, 2015, the Director of the Idaho Department of Water Resources (IDWR, Department) issued an order to staff directing them to convene a committee of experts to recommend specific technical changes to the "Second Amended Final Order Regarding Methodology For Determining Material Injury To Reasonable In-Season Demand And Reasonable Carryover" (Methodology) signed on June 23, 2010. Department staff created a committee in response to the Director's order composed of IDWR staff and experts representing parties involved in litigation of the Surface Water Coalition's (SWC) 2005 delivery call. In his January 30 order, the Director requested recommendations for technical changes to the Methodology by March 16, 2015, regarding the following specific issues:

1. Revising natural flow forecast methods for Twin Falls Canal Company.
2. Identifying more accurate and current crop data to determine crop water need.
3. Improving the mid-season reasonable in-season demand forecast.

Committee

The committee held multiple meetings and corresponded though email regarding the issues identified in the order. The committee comprises the following members:

Committee Member	Organization	Representing
Charles G. Brockway	Brockway Engineering	Surface Water Coalition
Chuck Brendecke	Lynker Technologies	Idaho Ground Water Users
Dave Shaw	ERO Resources	Surface Water Coalition
David Hoekema	IDWR	IDWR
Greg Sullivan	Spronk Water Engineers	City of Pocatello
Liz Cresto	IDWR	IDWR
Matt Anders	IDWR	IDWR
Scott King	SPF Water Engineering	Idaho Ground Water Users
Sean Vincent	IDWR	IDWR
Sophia Sigstedt	Lynker Technologies	Idaho Ground Water Users

The committee collectively decided that the most efficient method for consolidating member comments while still adhering to the March 16, 2015 deadline was to have committee members attach their comments to this memorandum. All of the committee members had an opportunity to review this memorandum and all of their comments that we received are attached in Appendix B.

Section 1 – Natural Flow Forecast

Background

The Methodology requires the Director to issue an order determining the demand shortfall of the SWC members for the irrigation season. The SWC members include A & B Irrigation District (A&B), American Falls Irrigation District #2 (AFRD2), Burley Irrigation District (BID), Milner Irrigation District (Milner), Minidoka Irrigation District (MID), North Side Canal Company (NSCC), and Twin Falls Canal Company (TFCC). The shortfall is the difference between the forecast supply and the forecast demand for each SWC member. The forecast supply is comprised of two components: the predicted natural flow supply and the predicted storage allocation for each SWC member. Pursuant to the Methodology, the Department undertakes an April forecast and mid-irrigation season forecast.

In the current Methodology, the April predicted natural flow supply is based on a regression analysis comparing the total natural flow in the Snake River near Heise between April and July to the annual natural flow diverted by each SWC member. While the Director only requested revisions to the natural flow forecast recommendations for TFCC, the committee also identified improved models for AFRD2, BID, MID, and NSCC through its work on revised natural flow forecast methods for TFCC. This memo includes recommendations for revising the April predicted natural flow supply forecasts for TFCC, AFRD2, BID, MID and NSCC.

The mid-irrigation season forecast is addressed in Step 6 of the Methodology. The forecast supply in Step 6 is the sum of the actual year-to-date natural flow diverted, plus the predicted natural flow supply for the remainder of the season, plus the actual preliminary storage allocation. The predicted natural flow supply for the remainder of the season was forecast by selecting an analogous year based on the Snake River Blackfoot to Milner reach gains. The selection of the analogous year typically occurred in August and a revised forecasted supply was issued. In working to meet the request of the Director's January 30 order, the committee reviewed a host of models that predict the natural flow supply for each SWC member from July 1 through October 31.

The natural flow supplies for each SWC member are comprised of natural flow in the Snake River passing the near Blackfoot gage and gains which occur in the Snake River between the Blackfoot to Milner reach. The committee reviewed several different models for predicting both the April and mid-season natural flow supply for each SWC member. While many different predictor variables were considered, the following variables were ultimately selected: natural flow in the Snake River near Heise as reported by the U.S. Bureau of Reclamation; snow water equivalent (SWE) data at the Two Oceans Plateau SNOTEL site; Box Canyon Springs discharge; Spring Creek discharge; and groundwater levels near American Falls Reservoir. The recommended model predictors vary by SWC member and by model implementation date (i.e. April 1 vs. July 1) and are summarized in the sections below.

April 1 Forecast

April forecast natural flow supply models were developed using data from 1990 through 2013. Data from 2014 was excluded from model development for two reasons: 1) the dataset for 2014 was still provisional at the time of model development and 2) record rainfall in August of 2014

resulted in significant data anomalies. For these reasons, we decided to exclude 2014 values from the dataset.

Both single linear regression and multiple linear regression models were considered. We recommend that natural flow supply forecast for A&B and Milner continue to be based on single linear regression models, in which the natural flow at the Snake River near Heise is the predictor variable. We believe the natural flow at the Snake River near Heise is a good predictor because A&B and Milner have relatively junior water rights and typically only divert natural flow during the spring runoff events. When applied, the April 1 forecast will utilize the U.S. Army Corps of Engineers and U.S. Bureau of Reclamation joint forecast of total natural flow in the Snake River near Heise from April-July. Alternative models were evaluated, but we found they added additional complexity without significantly improving the existing A&B and Milner models.

New multiple linear regression models are recommended to replace the existing regression models for TFCC, AFRD2, BID, MID, and NSCC. For these entities, the final predictor variables selected for their respective April 1 models included the total April through July natural flow in the Snake River near Heise and the total November to March discharge at Box Canyon Springs. The predictor variable, natural flow in the Snake River near Heise, was considered a good indicator of the natural flow supplied by snowmelt runoff. The predictor variable, Box Canyon Springs, was considered a good indicator for the natural flow supplied by the reach gains in the Blackfoot to Milner reach. If applied, the April 1 forecast models will utilize the U.S. Army Corps of Engineers and U.S. Bureau of Reclamation joint forecast of the natural flow in the Snake River near Heise from April-July.

Below is a table comparing the models used in the current Methodology to the recommended models. The recommended models for each member of the SWC have a better model fit (higher adjusted r^2) and a lower standard error than the models used in the current Methodology.

SWC Member	Models from Current Methodology[1]		Recommended Models	
	Adjusted r^2	Standard Error	Adjusted r^2	Standard Error
AFRD2	0.8317	39,700	0.8448	37,290
BID	0.7964	20,690	0.8546	17,100
MID	0.7896	29,710	0.8788	22,070
NSCC	0.8952	63,560	0.9151	55,950
TFCC	0.5416	71,990	0.8564	37,940

Appendix A contains graphs of the April models in comparison to the actual natural flow diversions for each SWC member.

July 1 Forecast

Step 6 of the Methodology requires the Department to issue a revised forecast supply "approximately halfway through the irrigation season". New natural flow predictor models have been developed for each SWC member for the specific period July 1 – October 31. We recommended that the July 1 models be implemented when revising the forecast supply in Step 6 of the Methodology.

Using data from 1990 to 2013, regression models were developed for A&B, AFRD2, and Milner by comparing snow water equivalent at the Two Oceans Plateau SNOTEL site on July 1 to the total

[1] Final Order Regarding April 2014 Forecast Supply, April 18, 2014.

natural flow diverted for the period July 1 through October 31. Data from 1997 was excluded from model development because of significant data anomalies as of a result of the high runoff year. The snow water equivalent at the Two Oceans Plateau SNOTEL site was considered a good indicator of additional natural flow diversions after July1. Years with zero (0) snow water equivalent on July 1 were excluded from the model dataset. It is recommended that in years with zero (0) snow water equivalent at the Two Oceans Plateau SNOTEL site on July 1, the predicted natural flow supply for the period July 1 – October 31 for A&B, AFRD2, and Milner will also be zero (0). For A&B, AFRD2, and Milner, the regression models would only be used in those years when the July 1 snow water equivalent at the Two Oceans Plateau SNOTEL site is greater than zero.

Multiple linear regression models were developed for BID, MID, NSCC, and TFCC. The regressions for BID, MID, and NSCC were developed with data from 1990 to 2013 and correlations were developed between the total natural flow diversions from July 1 through October 31and three predictor variables: (1) natural flow in the Snake River near Heise (April – June), (2) snow water equivalent at the Two Oceans Plateau SNOTEL site on June 15, and (3) March depth to water at well 05S31E27ABA1. Manual well measurements were historically taken from March 13 to March 30, with an average date of March 23. A transducer installed in May 2010 replaced the need for manual measurements. The combination of historical manual measurements and March 23 transducer readings will be utilized in the models.

The regression model to predict TFCC natural flow diversions from July 1 through October 31 relies on data from 1990 to 2013 and utilizes three predictor variables: (1) natural flow in the Snake River near Heise (April – June), (2) snow water equivalent at the Two Oceans Plateau SNOTEL site on June 15, and (3) Spring Creek total discharge (January – May). Below are summary statistics for the recommended models.

	Regression based on Two Oceans Plateau Snow Water Equivalent		Multiple Linear Regression	
SWC Member	Adjusted R^2	Standard Error	Adjusted R^2	Standard Error
A&B	0.9294	741		
AFRD2	0.8699	7,502		
BID			0.8932	11,480
Milner	0.6382	2,939		
MID			0.9037	15,720
NSCC			0.8615	46,930
TFCC			0.8511	29,270

Appendix A contains graphs of the July predictor models in comparison to the actual natural flow diversions for each SWC member.

Section 2 – Current Crop Mix Data

Current Method

Crop mix is one of the variables used in the current Methodology to calculate the crop water need of the SWC members. Crop mix is defined as the acreage of each crop type grown by each SWC member. The current method for determining crop mix is a three step process:

1) Tabular crop acreages from 1990 to the present are downloaded by county from the USDA National Agricultural Statistics Service (NASS).

2) Based on the tabular data available from 1990 to the present, an average crop mix for each county is determined.

3) The average crop mix of the counties is applied to each SWC member based on the proportion of land the SWC member has in each county.

Shortcomings of the current cropping pattern method include: NASS tabular data is adjusted to protect farmer privacy and is becoming increasing incomplete with fewer acreage totals being reported since 2005, average acreages for a 25-year period do not reflect current crop mix patterns, and county-wide crop mix may not represent the crop mix of SWC members.

Recommended Revision

Based on testing and with consideration of input from the committee, we recommend revising the method for determining crop mix. Instead of relying on county-wide tabular data, we propose using the digital Crop Data Layer (CDL) from the USDA National Agricultural Statistics Service (NASS). Benefits of this proposed method include: (1) using the most recent data available; and (2) restricting the geographic area of the data to the service area of each SWC member. The proposed method would involve the following steps each year:

1) Downloading the digital CDL dataset from the NASS website.

2) Removing crop type classification errors (speckling) in the CDL dataset with Zonal Statics in ArcGIS. A potential source of error associated with the Zonal Statics process is the intermittent availability of an annual field boundary dataset. However, our review of field boundary datasets and historical aerial photography revealed that field boundaries change infrequently and substituting field boundary datasets from previous years introduces minimal error. An additional possible source of error associated with the Zonal Statics process is the assignment of a single crop type to fields actually planted with multiple crop types. With respect to this concern our qualitative review of historical aerial photography and CDL datasets establishes that fields with multiple crops are rare and we conclude this concern represents a minimal source of error.

3) Clipping the CDL dataset in ArcGIS with an irrigated lands dataset for each SWC member.

4) Calculating the acreage by crop type for each SWC member.

5) Computing a 3-year average by crop type for each SWC member. In our analysis we have found the seven years of CDL data that are currently available do not depict a clear relation between cropping pattern and water supply. Because of this finding, a 3-year average appears adequate to reduce the influence of a single year while still being representative of the current cropping pattern.

Our comparison of the results of the tabular and CDL methods establishes that making this revision will cause the percentage of crop types identified for each SWC member to change between 0 and 30 percent (table below). This range of adjustment appears plausible given the change from a 20-year to a 3-year average and from a county-wide geographic area to the service areas of SWC members. A preliminary comparison of the crop water need calculated using the CDL and METRIC indicates the CDL and METRIC are in general agreement.

Comparison of Crop Mix Derived From NASS Tabular and NASS CDL.

Section 3- Reasonable In-Season Demand (RISD)

The committee began discussions on improving the mid-season reasonable in-season demand forecast. With the limited timeframe the committee was given, we were unable to conclude an analysis of methods to improve RISD forecasts. Because this analysis is not yet complete, we cannot currently recommend any changes to the current Methodology regarding this issue.

Section 4 – Future Committee Meetings

Committee members provided valuable technical input for revising the Methodology. We recommend continuing to convene this committee in the following manner:

1) At least one annual meeting to review implementation of the Methodology during the previous irrigation season. This would be an ongoing forum for identifying and reviewing potential technical revisions to the Methodology.

2) Multiple meetings during 2015 to finish reviewing the following subjects that were discussed by the committee, but require further discussion and analysis to develop a recommendation:

    a. Mid-season calculation of reasonable in-season demand (RISD): The current method uses average demand in 2006/2008 to predict the RISD for the remainder of the irrigation season. We are analyzing the potential for refining this predication by selecting a representative historical analogous year(s).

    b. Supplemental ground water use: There was insufficient time for the committee to evaluate this subject.

    c. Project efficiency: The project efficiency variable used in the RISD calculation has not been updated since the Methodology was originally developed. The committee had preliminary discussion about the need to update project efficiency and committee members expressed interest in providing input.

    d. Irrigated acres: Significant discussion focused on this topic and it was generally agreed that the process for determining irrigated acres for SWC members could be improved.

APPENDIX B

Comments Received From Committee Members

MEMORANDUM
Settlement Document Subject to I.R.E 408

To: Liz Cresto

From: Charles Brendecke and Sophia Signodi

Subject: Comments on Staff Recommendations

Date: March 16, 2015

This memorandum addresses our comments on the analyses presented to the Technical Working Group related to revisions to the Methodology Order for determining injury to water rights held by members of the Surface Water Coalition. It serves as an addendum to the Idaho Department of Water Resources (IDWR or Department) staff memorandum regarding recommended revisions. Department staff were asked to provide recommendations to the Director on the following topics[1]:

1. Revised natural flow forecast methods for Twin Fall Canal Company (TFCC)
2. Identify more current and accurate crop data to determine crop water need.
3. Improvement of mid-season reasonable in-season demand forecast (RISD)

Topics 1 and 2 were assigned priority and due to time constraints are the only topics the Department staff make recommendations on in their memorandum.

Sections 1 and 2 below summarize our comments based on the proceedings of the committee regarding the recommendations to topics 1 and 2, respectively, in the staff memorandum. It is our understanding that Department staff recommendations on topics 1 and 2 are based on analyses that could be completed within the time constraints provided, and that while they are intended to provide guidance for administration of TFCC's water rights for the 2015 irrigation there will be opportunity for further analyses and recommendations concerning both topics for future irrigation seasons. It is also our understanding further work will be done on topic 3 prior to the need for the mid-season adjustment. Section 3 summarizes our preliminary comments regarding aspects of the mid-season RISD calculation.

The three topics identified above are not the only items in the Amended Methodology Order that were set aside or remanded by the District Court. The comments in our memorandum should not be considered a comprehensive summary of our opinion on all the technical aspects under consideration in the remand of the Amended Methodology Order.

Section 1

Part D. of the Memorandum Decision and Order on Petitions for Judicial Review of the Amended Methodology Order found that "The *Methodology Order's* reliance upon the Joint Forecast, and its use of the Heise Gage, to determine the available water supply for Twin Falls Canal Company is set aside and remanded for further proceedings as necessary." The issue was unopposed and the Department expressed that the Joint Forecast is "not the best evidence" for purposes of predicting TFCC's supply and that they would be willing to work with TFCC to improve the predictors for future application.

The Department staff's recommendations for revised natural flow forecast methods for TFCC began with the assumption that the need to predict TFCC's supply must occur prior to April 1. The comments provided here neither support nor reject that assumption. The Department staff' recommendations for revising TFCC's supply improves the current relationship used in the Methodology Order. However the analysis and committee review process was undertaken in a highly compressed timeframe and many things warrant additional consideration. We support the idea of treating the refinements to the Methodology Order as a "living document" that allows for continual improvement and to use the staff's recommendation as an interim solution for the upcoming 2015 irrigation season only.

We believe that one reason the Heise Gage forecast is not a good predictor for TFCC supply is that the predictor is physically based while the TFCC supply is considered to be the historical TFCC diversion record. TFCC diversions are not the same as the physical supply available to TFCC because the diversions reflect administrative and operational influences in addition to being a condition of the physical natural flow supply. For example, TFCC has the more senior water right relative to the other surface water diverters below Blackfoot and their diversions in early season are often capped by the water right amount rather than the physically available supply. The water right cap creates a non-continuous and non-normally distributed dependent variable in the regression analysis. This difference is a probable reason the Heise forecast alone had such a low correlation to TFCC compared to the other entities. In light of this, an approach that we believe should be further investigated is creating a regression relationship or alternative model that forecasts the physical natural flow supply with subsequent allocation of that physical supply among the rights of the SWC.

The natural flow forecasts for TFCC and subsequently a selection of other entities were improved by moving from a single variable linear regression model to a multilinear regression. The improvement in the TFCC prediction supports the Department staff recommendation in the use of the additional Box Canyon data in April and the Snotel and Spring Creek discharge data in July. The Department Staff also recommended new models for some entities that showed improvement in the July forecast with the addition of Snotel and March groundwater level data. While these newly developed models can be tested over the upcoming irrigation season we believe they can be further improved.

Section 2

Our comments are limited on the succinct issue of the Department staff recommendation to use the digital Crop Data Layer (CDL) from the USDA National Agricultural Statistics Service (NASS) as a more current and accurate crop data source to determine crop water need. One concern here is how the data is post processed. We recommend sensitivity tests to different program settings when raster processing is applied. We also recommend further investigation into the method behind the development of the NASS dataset to determine how and to what extent the data set is field verified or if there are common misrepresentations that should be considered in the process of data quality assurance checks.

Section 3

As the Department memorandum stated there was not sufficient time for the staff to make a recommendation on the RISD forecast. There are multiple components to the RISD forecast calculation that are under review in the current Methodology Order. These include but may not be limited to:

- The mid-season calculation of RISD
- Project efficiency
- Irrigated acres
- Supplemental groundwater use

Regarding the mid-season calculation of RISD the sensitivity and appropriate use of crop coefficients and climate data behind the reference ET in the calculation should be investigated and analyzed for proper application to local conditions.

Regarding project efficiencies we recommend investigation into trends among the entities related to each of the factors the Methodology Order considers in their determination.

Regarding irrigated acres it appears there is not a standard review process for the updates by the SWC or for the critique by IDWR of the submittal of the irrigated acres. With only a check against the total acres in the decreed place of use, there is little or no incentive to keep these shapefiles up to date. Based on the discussion in the technical working group the determination of irrigated acres will likely not be addressed in this review process. Updating irrigated acres by verification of claimed irrigated polygons by satellite and/or aerial imagery is a detailed, time consuming process. But it is essential to protect the valid water rights of juniors.

If SWC members are going to be responsible for this task a first step that the Department should take is to develop a standardized method for this update. This should include pointers to the preferred irrigated polygon base layer, satellite/aerial imagery, and a comprehensive list of items that need to be clipped out (i.e. roads, homesteads, brush land, fallow acres, water features, urban areas, sub-divisions), how alignment issues could be improved and recommendations for how to streamline as many of these processes as possible. This process will only be fair if each user does the analysis in the same way. Once a more accurate representation of the irrigated acres for each entity is created and approved updates in the future can be based more on accounting of the movement of water throughout the district as some of the entities already track. The 5% change standard should also be considered in light of large districts like TFCC where a 5% error

in irrigated acres can result in calculation of tens of thousands of acre-feet of erroneous mitigation obligation.

Regarding supplemental groundwater use there was not sufficient time for the working group or Department staff to address this issue. However, it was one of the specific technical items cited for revision by the District Court. Accordingly, we believe that the process that has been established for identifying Methodology revisions be continued until all the technical issues presented in the remand are addressed.

SPF WATER ENGINEERING

MEMORANDUM

DATE: March 16, 2015

TO: Liz Cresto, Technical Hydrologist

FROM: Scott King, P.E., SPF Water Engineering LLC on behalf of IGWA

RE: **Comments on Staff Recommendations**

Job: **535.0190**

Liz,

This memo provides comments to be included with your March 16, 2015 Settlement Document Memorandum.

1. The committee discussed the importance of methodology guidance being a living document and that the Technical Working Group (TWG) should continue meeting occasionally to improve the methodology and address items that were neglected due to limited time. I want to express my support for this approach.

2. Supplemental ground water use was a topic of importance to the Technical Working Group's (TWG), but was not evaluated sufficiently due to time constraints. Supplemental ground water use within much of the surface water coalition's delivery area is measured and reported to IDWR. However, we expect not all ground water use is measured due to the wells being located outside of the ground water measurement program area. Unmeasured supplemental ground water use should be addressed and may need to be measured.

3. The total area of lands receiving surface water irrigation deliveries has been updated for some but not all SWC members. The TWC discussed a methodology whereby irrigated acres would be updated if that area changed more than five percent from currently used values. A five percent change is significantly different when comparing between the smaller and larger delivery entities. For example, five percent approaches ten thousand acres for Twin Falls Canal Company. The committee may consider also including an acreage threshold in this decision point. For example: "the lesser of five percent or one thousand acres." This approach is supported by high quality aerial imagery currently available, limited land use changes within the SWC areas, and prior efforts in identifying and digitizing irrigated and non-irrigated areas.

300 E. Mallard Drive, Suite 350, Boise, Idaho 83706 Tel: 208-383-4144 Fax: 208-383-4158

4. Some delivery entities have reported that irrigated acres are unchanged from decreed values. There is not an incentive for SWC entities to identify and report reductions in irrigated acres. This deficiency should be addressed.

Thank you for the opportunity to participate in the committee and provide these comments.

Memorandum Subject to I.R.E. 408

To: Gary Spackman, Director IDWR

From: Charles G. Brockway, Brockway Engineering on behalf of the SWC
David Shaw, ERO Resources Corp. on behalf of the SWC

Date: March 18, 2015

Re: Recommended Revisions to the Second Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover

The SWC generally supports the efforts of the Director, IDWR Staff and other members of the TWG for their efforts and the recommendations proposed in the staff memorandum to the Director dated March 16, 2015. The recommended natural flow forecasting methods and crop mix determination are improvements to the original methodology procedure and we urge the Director to implement those changes. We also support the annual review of the implementation of the Methodology.

In the second paragraph under the April 1 Forecast section the statement is made that A&B and Milner irrigation districts have relatively junior priority water rights and typically only divert natural flow during spring runoff events. We believe it would be worth noting that Milner's priority is good enough to sometimes divert natural flow at other times, particularly late in the irrigation season.

The SWC supports the use of the NASS CDL data to estimate crop mix for the current year based on the 3 previous years' data. We notice in the example on page 6 of the staff memo the average used is for 2011 – 2013. We assume this is the result of a timing issue since the 2014 CDL was not released until after January 1, 2015. We assume the intent is to use the most recent 3 years' data when used to calculate RISD in the Methodology process. We also want to ensure the SWC Managers can submit crop mix data that becomes available to them if they believe any particular year is an anomaly and would not be fairly represented by the previous 3 years' CDL data.

The SWC is concerned about the topics in the final recommendation for multiple meetings for the remainder of 2015. Most of the proposed topics are not part of the Court's remand order. In particular, project efficiency was fully supported by the court in spite of the ongoing efforts by others to attack that aspect of the methodology or the efficiencies themselves. On remand the Court simply said the Director should follow the order when considering irrigated acreage submitted by members of the SWC. We understand the need to change the water supply forecasting methods to make a mid-season determination and the July 1 methods in the staff memorandum address that need but there has not been a compelling reason given to change the method of estimating demand for the remainder of the year.

Again, thank you to everyone who participated and to the Director and his staff for the opportunity to participate in this effort.

ATTACHMENT B:

LYNKER MEMORANDUM: COMMENTS ON 2022 IDWR STAFF RECOMMENDATIONS

MEMORANDUM

To: Matt Anders and Kara Ferguson, IDWR

From: Sophia C. Sigstedt, Lynker

Subject: Comments on 2022 IDWR Staff Recommendations

Date: January 16, 2023

This memorandum addresses my comments on the analyses presented to the 2022 Technical Working Group (TWG) related to revisions to the Methodology Order for determining injury to water rights held by members of the Surface Water Coalition. It serves as an addendum to Idaho Department of Water Resources (IDWR or Department) staff recommendations for the 2022 Methodology Update. IDWR staff and other members of the TWG presented analyses and recommendations regarding the following topics:

1. Baseline Year (BLY)
2. Forecasting Natural Flow Supply
3. Near-Real-Time METRIC for ET
4. Project Efficiency (PE)
5. ESPAM2.2 Steady State v. Transient

IDWR staff proposed changes related to BLY and PE, but only presented the results of internal analysis without recommending changes to the other topics investigated. TWG members were asked to consider whether the proposed recommendations provide a better technical basis than the current technique, or if there was an alternative with a better technical basis.

Sections 1-5 summarize my comments based on the proceedings for each TWG topic as listed above, respectively.

The topics identified above are not the only items in the Amended Methodology Order that should be considered regarding technical improvements. The comments in this memo are primarily in response to recommended changes made by IDWR staff in their memorandum dated December 23rd, 2022[1] and should not be considered a comprehensive summary of my opinions on all the technical aspects presented to the TWG or any other outstanding issues in the proceeding.

Section 1: Baseline Year Update

The IDWR staff recommended:

- Update the BLY irrigation demand used to determine Reasonable In-Season Demand (RISD) from the current average of diversion demands for the 2006, 2008, and 2012 (06/08/12) irrigation seasons to the diversion demand for the 2018 irrigation season.
- Update the BLY irrigation demand used to determine Reasonable Carryover for each SWC member from the current average of diversion demands for the 06/08/12 irrigation seasons to the diversion demand for the 2018 irrigation season.

[1] Summary of Recommended Technical Revisions to the 4th Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover for the Surface Water Coalition (IDWR, December 23rd 2022)

Lynker
5445 Conestoga Court, Suite 100
Boulder, Colorado 80301

In my opinion the recommendation to replace average diversions for the 06/08/12 irrigation seasons with single-year diversions in 2018 as the BLY does not have an adequate technical basis, and alternatives should be considered due to the following:

1. IDWR should consider rank within the period-of-record (POR) and select an average of years closer to the rank of the 06/08/12 BLY selected in 2015. IDWR staff presented analysis to the TWG for individual years 2018 and 2020 for consideration as the updated BLY. Either of these individual years are inadequate to represent reasonably dry baseline conditions for SWC diversions.

   When the average of diversion demands for the 06/08/12 irrigation seasons was selected as the BLY in 2015, the 06/08/12 average ranked between 7th and 8th highest for diversions, or about the 55th percentile (based on a normal distribution), for the POR 2000-2015 (**Figure 1**). IDWR staff presented analysis of Demand Shortfall calculations using 2018 and 2020 as an alternative BLY as they were both found to individually meet all the BLY criteria as shown in **Table 1**. For the POR 2000-2021 the diversion demand for 2018 and 2020 rank 3rd and 2nd, respectively, highest for diversions out of the 22 years, or about the 90th and 95th percentile (based on a normal distribution) for the POR (**Figure 2**).

   In a hindcast analysis by IDWR staff, the higher rank in BLY SWC diversions appears to cause a huge shift in the type of water year (i.e. wet, average, dry, very dry) where Demand Shortfalls are calculated. The hindcast showed a Demand Shortfall much more frequently in average and even wet years in addition to every dry or very dry year. When you compare the distribution of SWC total diversion demands for the POR 2000-2015 compared to 2000-2021 in **Figures 1** and **2**, however, it is apparent that they are very similar with mean diversions of 3.16 maf and 3.2 maf, respectively. The standard deviation is also very similar for the POR 2000-2015 compared to 2000-2021 at 178,089 af and 178,587 af, respectively. The selection of the BLY is meant to be conservative as defined by the BLY criteria. The shift to SWC diversions of a much higher rank (compared to the previous BLY) like 2018 or 2020 translates to a much higher level of conservatism and is not technically justified given the similarity between mean diversions and the standard deviation for the 2000-2021 POR versus the 2000-2015 POR.

   The Methodology Order states that the BLY can be a year or an average of years that meet the BLY criteria (**Table 1**). IDWR staff considered rank within the POR when they recommend keeping the 2002 and 2004 average Heise natural flows as the Supply in the Reasonable Carryover calculation from the 4th Amended Methodology Order for the 2022 update[2]. The average of diversion demands for the 2006 and 2018 (06/18) irrigation seasons meet all the BLY criteria as shown in **Table 1** and is closer to the 55th percentile based on a normal distribution for diversions 2000-2021 similar to the rank of the BLY 06/08/12 (**Figures 1** and **2**) as applied in the 4th Amended Methodology Order. The BLY of 06/18 has a better technical basis than the proposed update to 2018 as the BLY.

Table 1. Baseline Year and Baseline Year Criteria

BLY Criteria	BLY Avg 06/18	BLY 2018	BLY 2020	Avg 2000-2021
Abv Avg SWC Diversions	3.22 maf	3.38 maf	3.53 maf	3.20 maf
Abv Avg GDD	2575 units	2550 units	2600 units	2495 units
Abv ET	1265 mm/d	1275 mm/d	1280 mm/d	1245 mm/d
Blw Avg Precipitation	3.9 in	2.6 in	2.7 in	4.5 in
Abv Avg SWC Supply	8.52 maf	9.00 maf	8.10 maf	7.70 maf

Boulder, Colorado 80301

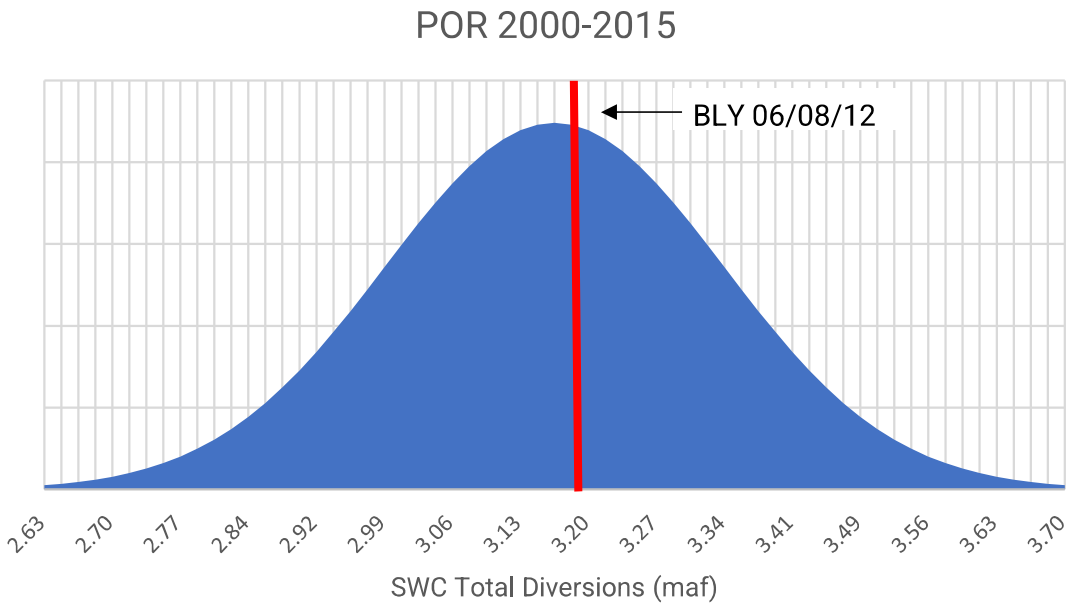

Figure 2. Normal distribution of SWC Total Diversion over the POR 2000-2015, the *red line* shows where the selected BLY 06/08/12 for the 4th Methodology Order falls within the normal distribution.

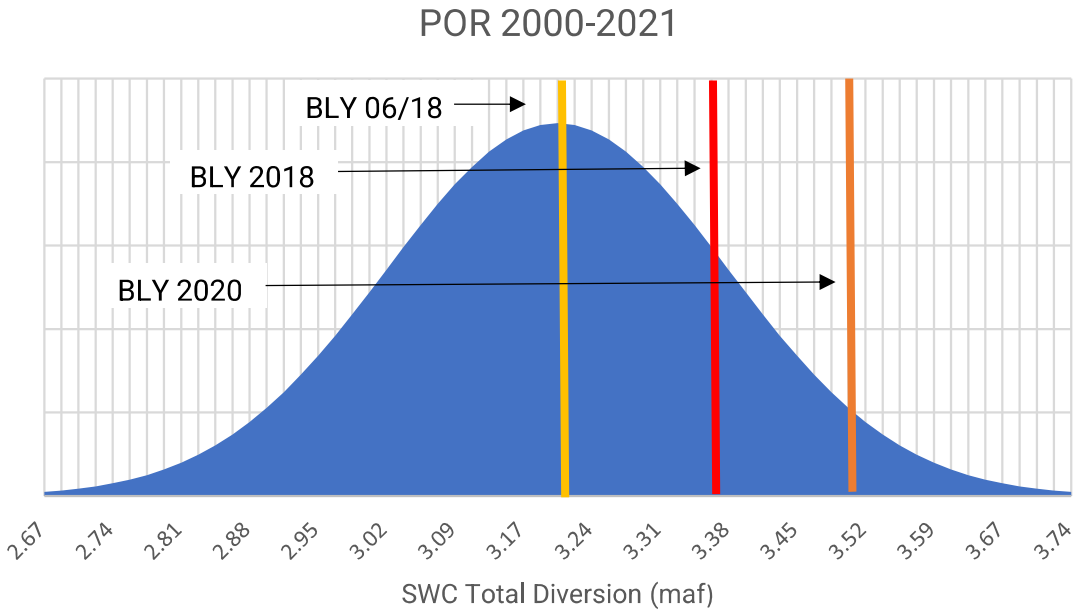

Figure 2. Normal distribution of SWC Total Diversion over the POR 2000-2021, the *yellow line*, *red line*, and *orange line* show where the proposed BLY 06/18, 2018 and 2020 falls within the normal distribution, respectively.

Lynker
5445 Conestoga Court, Suite 100
Boulder, Colorado 80301

2. Another reason a better alternative would be to use diversion demands for the 06/18 irrigation seasons for the BLY is that there were unique hydrologic circumstances in 2018 that I don't believe represent the typical dry year. The 2017/2018 snowpack was very high and water year forecasts and early season streamflow led to positive water supply forecasts which resulted in a record amount of aquifer recharge in 2018. IDWR staff acknowledged the technical difficulties in sorting out surface water adjustments like recharge in applying the Methodology Order. The combination of large volumes of widely distributed canal recharge, often in relatively rarely used or new systems, may have exacerbated uncertainty in the adjustment. The positive water supply outlook may have also resulted in less stringent surface water administration and ultimately higher diversions than the crop water need alone would predict. Consequently, using gross diversions in 2018 as the BLY effectively overstates surface water irrigation demand. IDWR staff presentations and a review of Twin Falls Agrimet station data also showed the 2018 irrigation season is the only year in the 1992-2021 POR with a zero-precipitation total for July-September. The fact that almost any individual water year will have some unique circumstance is a good reason for continuing to define the BLY based on an average of years as the Methodology Order does currently.
3. An additional reason for using a specific percentile (or rank) within the POR when establishing a BLY, and for using an average of years, is that the process for selection of the BLY otherwise appears arbitrary and subjective. If IDWR staff are presented with multiple years within the POR that fit the criteria for a BLY, and there is no guidance or standard method for selecting a single BLY, the ultimate selection becomes purely subjective. Using an average of years that targets a prescribed rank is a more objective and technically defensible process.

Section 2: Forecasting Natural Flow Supply

IDWR staff did not make a recommendation on updating April and July regression models to improve their predictive power for natural flow supply. The staff did make presentations to the TWG on natural flow forecasting models that showed the Twin Fall Canal Company (TFCC) model is degrading in the R^2 value. This degradation is significant in that the R^2 values is an expression of the explanatory power of the forecast model. The TFCC natural flow forecast models also started with the lowest R^2 values based on the previously revised forecast. The technical information presented to the TWG indicated that a revised natural flow method for TFCC should be evaluated and a recommendation for an improved method should be made. However, given the extremely compressed timeframe for staff and TWG members to conduct a thorough evaluation I understand why a recommendation was not made at this point.

Lynker's technical memorandum included as addendum to IDWR staff recommendations in 2015[3] laid out an alternative forecast model approach that I continue to think should be further investigated. The approach is creating a regression relationship or alternative model that forecasts the physical natural flow supply with subsequent allocation of that physical supply among the rights of the SWC. The technical basis for this suggestion is that water rights administration creates a non-continuous and non-normally distributed dependent variable in the regression analysis. This is likely the reason it is difficult to find a high performing regression model for TFCC.

The process for natural flow forecast model revision should also be standardized in-terms of defining how frequently a thorough re-evaluation of the predictors and models is done (i.e. 3-yrs, 5-yrs, if R^2 value drops below a threshold). This should include re-evaluating previously tested predictors over the new POR, as well as, casting a new net of total predictors for consideration by the TWG. While the TFCC model stands out in needing a refinement all of the models could be improved if sufficient time for the analysis were allowed. Several of the models utilize a depth to groundwater measurement as a predictor from a specific Sentinel Well flagged by a separate TWG (IGWA-SWC)[4], as likely impacted by American Falls Reservoir level.

Boulder, Colorado 80301

Section 3: Near-Real-Time METRIC for ET

The IDWR staff did not make a recommendation on utilizing near-real-time METRIC for determining Crop Water Need (CWN) in the RISD calculation. The application of METRIC in the determination of crop demands deals with a complex dataset that requires complex processing. Given the magnitude of the task to incorporate METRIC data I understand the staff not making a recommendation at this time. The IDWR staff should keep track of the calculation utilizing the METRIC data in parallel to the current CWN calculation method as way to continue to evaluate its use. The Department's Eastern Snake Plain Aquifer (ESPA) model already utilizes METRIC data for consumptive use calculations used for model input data. Given the complexity of the METRIC data I also recommend further investigation into the method behind the calibration and processing of the dataset to determine how and to what extent the METRIC data can be validated at the field-scale or if there are common misrepresentations that should be considered in the process of data quality assurance checks. This should be done in coordination with validation efforts by the Department on their ESPAM Metric calibration and processing.

The IDWR staff presentation regarding near-real-time METRIC application identified a significant shortcoming in the current method for calculating CWN as the fact that the most up-to-date crop data is from the previous year and that SWC irrigated acre datasets sometimes represent service areas, not the actual irrigated land[5]. Non-irrigated acres should not be considered in determining the irrigation supply necessary for SWC members[6]. The METRIC data could first be used to create a standard review process for the Methodology Order Step 1 submittal of irrigated acres by the SWC entities. IDWR staff should use a precise determination of irrigated acreage irrespective of whether it uses METRIC in the calculation of CWN. With IDWR staff only checking against the total acres for the decreed place of use, there is little to no incentive to keep the spatial data for the irrigated acres up to date. The METRIC data would be available for the current irrigation season and can be used to assess actual irrigated land. Some of the preliminary analysis by IDWR staff using METRIC data illustrated that through processing they were able to identify about 15,000 acres within the TFCC irrigated acres dataset that should not qualify as irrigated. The mischaracterized acres were all minor areal corrections but over a large service area such as TFCC added up to a significant amount of erroneous total acres. This just highlights the importance of spending the time to get an accurate picture of irrigated acres for an accurate RISD calculation. As previously noted in Lynker's 2015 comment letter the 5% change standard for SWC submittals should be reconsidered in light of large districts like TFCC where a 5% error in the irrigated acres can result in calculation of tens of thousands of acre-feet of erroneous mitigation obligation. Liz Cresto an IDWR staff member on the TWG in 2015 also made a similar recommendation in her comment letter attached to the staff memorandum.

Neither the 2015 nor the 2022 TWG has provided an opportunity to address concerns regarding supplemental groundwater use. This is a critical aspect of the RISD calculation and was one of the specific technical items cited for revision by the District Court. Analysis of supplemental groundwater use is likely critical to accurately applying METRIC in the RISD calculation.

Section 4: Project Efficiency

The IDWR staff recommended:

- Update the project efficiency value used to calculate monthly reasonable in-season demand from a rolling average of the previous eight years to a rolling average of the previous fifteen years.

[5] Proposed Modification to Method for Determining Reasonable In-Season Demand for the Surface Water Coalition: Use of the Near Real Time Metric (IDWR, presentation slide no. 8, November 17th 2022)

[6] Second Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover-pg 4

Lynker
5445 Conestoga Court, Suite 100
Boulder, Colorado 80301

The technical basis for the IDWR staff recommendation was based on there being an extended POR available. TWG discussions and subsequent presentations identified other issues that should be considered in Methodology applications of project efficiency (PE) to RISD calculation.

1. There is higher uncertainty in the April and October project efficiency values. April and October represent months during the irrigation season when the method of calculating RISD strictly as a function CWN and PE is less reliable because CWN is often not the driving factor in diversions[7].
2. Project efficiency among SWC entities are almost all flat or declining (6 out of 7 entities), which is contrary to what would be expected with technology advancements and constrained water supplies[8].

Change in Project Efficiency (2001-2021) (percentage point change)	
A&B	-4.6%
AFRD2	-3.6%
BID	-1.0%
Milner	-12.6%
Minidoka	+12.2%
NSCC	-3.0%
TFCC	+1.8%

3. Scatter plots by SWC entity comparing Annual Crop Water Need to Annual Diversions show Crop Water Need is limited as a predictor given the low explanatory power indicated by the low R^2 values in the analysis[9].

Regarding the mid-season calculation of RISD, the sensitivity and appropriate use of CWN as a predictor for in-season demands for SWC entities should be evaluated. Technical analysis to the TWG showed that this is not a strong relationship[10]. This disconnect should be evaluated by the TWG so a recommendation can be made. The trends in declining PE are concerning in that they are contrary to our expectations given the direction technology advancements and constrained water supply. The declines in PE are significant in that any decline in PE will result in increased demands and subsequently increased calculated Demand Shortfalls. The IDWR staff presentation on PE illustrated how the very minor change in PE resulting from extending the POR for the average translated to tens of thousands of acre-feet differences in the Short Fall determination[11]. Sullivan (e-mail to TWG 12/21/2022) found that when analyzing monthly PE the low PE in some months cause monthly demands calculated based on CWN/PE to be very sensitive to changes in CWN. I agree with Sullivan's recommendation that given the outside influences and uncertainty in some of the monthly PE values IDWR staff should consider using a seasonal PE value in computing monthly diversion demands. I also agree with Sullivan's recommendation that consideration should be given to PE values that better reflect reasonable and efficient operations of SWC members. Given the observed declining trends in PE and the historically wide range in operational PE by entity it is hard to know when SWC supplies are short under reasonable and efficient operations. This is consistent with Lynker's 2015 recommendation for an investigation into trends among entities related to PE factors.

[7] Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover-pg 18
[8] Greg Sullivan e-mail, Updated Comparison of Adjusted Diversion and Crop Water Needs for SWC Members, to TWG December 21, 2022
[9] Analysis in Greg Sullivan datasheet "2022-12-21 SWC Diversions and CWN.xls"
[10] Analysis in Greg Sullivan datasheet "2022-12-21 SWC Diversions and CWN.xls"
[11] Proposed Modification of the Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover: Project Efficiency (IDWR, presentation slide no. 15, November 28th, 2022)

Lynker
5445 Conestoga Court, Suite 100
Boulder, Colorado 80301

Given the compressed timeframe around the 2022 TWG meeting there was not sufficient time for the TWG members to analyze or address these outstanding issues. Additional time should be set aside for the TWG to conduct an analysis and make a recommendation.

Section 5: Steady State v. Transient

The Department staff did not make a recommendation on using transient model simulation for determining curtailment priority dates in the Methodology. The IDWR staff presented to the TWG the following:

1. Technically the steady state application is not consistent with the variable curtailment dates and mitigation volumes under the Methodology.
2. Transient analysis shows that in-season shortfalls can generally not be met at Time of Need by in-season curtailment.
3. There is a huge difference in resulting determination of the curtailment priority date if a steady state v. transient model is applied.
4. Under a transient model application any Demand Shortfall above ~100K af would result in aquifer wide curtailment

It is not clear what additional analysis the Department staff need to conduct to make a recommendation on steady state v. transient model application. What is clear is that this represents a huge uncertainty to the water users and how they make planning and management decisions moving forward.

1.0 INTRODUCTION

1.1 Objectives

The objective of this report is to review the hydrology, water rights and groundwater modeling of the Eastern Snake Plain Aquifer (ESPA) in the vicinity of the Rangen, Inc., (Rangen) aquaculture facility, as they relate to the delivery call placed by Rangen on December 13, 2011. That delivery call requests the curtailment of all groundwater rights within the domain of the Enhanced Snake Plain Aquifer Model (ESPAM) that are junior to July 13, 1962. The primary study area of focus of this report is shown on Figure 1.1.

1.2 Organization of Report

This report is organized into 6 sections, beginning with this Introduction and Summary of Conclusions. Section 2 presents an overview of hydrology and water development in the area of the Rangen facility. Section 3 provides a detailed description of the Rangen facility itself and the water rights pertinent to it. Section 4 describes development and calibration of the ESPAM Version 2.1 (ESPAM2.1) by the Idaho Department of Water Resources (IDWR). Section 5 describes analysis of the effects of curtailment of junior groundwater rights using ESPAM2.1 and its predecessor, ESPAM2.0. Section 6 presents an analysis of curtailment effects using a modified version of ESPAM2.1 that more closely reflects hydrogeologic conditions near Rangen.

A related discussion of hydrogeology of the Rangen area is presented in Hinckley (2012).

1.3 Summary of Conclusions

Based on the analyses and evaluations I carried out in preparing this report, I conclude that:

1. The Martin-Curren Tunnel is a distinct source of water separate from natural springs that also supply Rangen.
2. The July 13, 1962, Rangen water right that is the basis of the delivery call (36-2551) is sourced at the Martin-Curren Tunnel.
3. The April 12, 1977, water right (36-7694) held by Rangen is sourced at the Martin-Curren Tunnel.
4. The Martin-Curren Tunnel is an artificial excavation that was constructed to access groundwater for irrigation purposes.
5. The Martin-Curren Tunnel meets the physical definition of a well contained in Idaho Code 42-230(b).
6. Neither observed nor estimated flows from the Martin-Curren Tunnel have ever been high enough to provide water in-priority to the 1977 water right (36-7694) held by Rangen.
7. Observed flows of Billingsley Creek reported by Rangen have not been high enough to provide any water to Rangen's 1977 water right (36-7694) since October of 1976, a date which precedes the priority of the water right.
8. Inspection of Rangen facilities and diversions by the Department of Water Resources concluded, among other things, that water right 36-7694 "should not have been issued."

9. Water right 36-7694 has never been able to divert and beneficially use water in priority.
10. Neither observed nor estimated flows from the Martin-Curren Tunnel have ever been high enough to deliver the maximum rate of diversion authorized under water right 36-2551.
11. Rangen's measurement of water flows through its property underestimates actual flows by 10-12%
12. It is feasible for Rangen to make more efficient use of available flows by delivering water from Billingsley Creek to its small raceways.
13. As a result of incidental recharge from surface water irrigation, spring flows in the Milner to King Hill reach are currently 25 percent greater than natural, pre-development flows.
14. Much of the change in spring discharge in the Milner to King Hill reach since 1960 can be attributed to reduction in incidental recharge from surface water irrigation due to changes intended to reduce waste.
15. Neither ESPAM 2.1 nor its predecessors is capable of separating the effects of groundwater pumping on flows from the Martin-Curren Tunnel from the effects of groundwater pumping on flows from other springs in the Rangen complex. .
16. The predictive uncertainty analysis of ESPAM2 and ESPAM2.1 carried out by the IDWR explores only a limited aspect of model uncertainty and does not quantify overall model uncertainty.
17. Fundamental to overall model uncertainty is the uncertainty associated with the conceptual model reflected in ESPAM2.1. The predictive uncertainty analysis relies on a single conceptual model and does not explore the uncertainty that arises from improper conceptualization of local geologic and hydraulic conditions that influence discharge of specific spring complexes, such as those at Rangen.
18. Alternative conceptual models can be developed that better reflect hydro-geologic conditions near Rangen and which produce substantially different effects of curtailment than does ESPAM2.1.
19. That ESPAM2.1 can fairly closely mimic the observed past behavior of a spring complex is not proof that it represents hydrogeologic reality sufficiently to predict accurately future behaviour of that complex, especially under aquifer water use conditions (e.g., curtailment of junior groundwater pumping) that are radically different from those extant in the model calibration period.
20. The ESPAM2.1 is not sufficiently detailed in either its general formulation or its representation of hydrogeologic conditions at Rangen, to be used reliably to predict changes in flow available to water right 36-2551 due to curtailment of junior groundwater rights on the ESPA.
21. ESPAM2.1 represents the details of the Rangen spring complex and the surrounding geology in highly simplified form, omitting several key features and that would make significant differences in predicted benefits of curtailment.
22. Using ESPAM2 and ESPAM2.1, less than 3 % of the curtailed groundwater rights junior to Rangen's 1962 priority, under the 10% trimline, would accrue to the Rangen complex; the rest would accrue to other connected river reaches, springs and baseflows, including those on which there are no water rights or diversions, those on which there are no delivery calls, those on which

approved mitigation plans are already in place, and those on which diversions occur under water rights junior to those of the curtailed rights.

23. An even smaller amount of the curtailed water use described in conclusion (23) above would accrue to the Martin-Curren Tunnel.

24. Using ESPAM2, less than 1% of the curtailed groundwater rights junior to Rangen's 1962 priority over the entire model domain, such as requested by Rangen, would accrue to the Rangen complex, the rest accruing to other connected river reaches, springs and baseflows, including those on which there are no water rights or diversions, those on which there are no delivery calls, those on which approved mitigation plans are already in place, and those on which diversions occur under water rights junior to those of the curtailed rights.

25. Because the model domain, irrigated lands and water rights are the same in ESPAM2.1 as in ESPAM2, conclusion (25) above would also apply to results from ESPAM2.1.

26. An even smaller amount of the curtailed water rights described in conclusion (25) above would accrue to the Martin-Curren Tunnel.

27. Alternative calibrated models that better reflect hydro-geologic conditions near Rangen show that curtailment of groundwater rights, within the 10% trimline and junior to Rangen's 1962 right, would produce only half, and possibly as little as 5%, of the benefit to Rangen predicted by ESPAM2.1.

28. Analysis using ESPAM2.1 shows that implementation of Rangen's request for widespread curtailment will, by any reasonable standard, result in waste of the water resource.

29. If the Director uses ESPAM2.1 to quantify the benefits to water right 36-2551 from curtailment of junior groundwater uses, this quantification should reflect the substantial uncertainty of that benefit that derives from use of a regional model to predict discharge from a particular spring outlet at the edge of the aquifer system. Due to this uncertainty, any curtailment based on ESPAM2.1 should be limited to junior-priority rights for which ESPAM2.1 predicts a significant benefit to Rangen. In my opinion, to recognize uncertainty and prevent unreasonable waste, application of ESPAM2.1 should at a minimum restrict curtailment to junior rights for which ESPAM2.1 predicts at least 10% of the curtailed water will accrue to Rangen.

30. Even use of a 10% trimline results in waste of the water resource because the vast majority of that foregone use would not accrue to the benefit of Rangen.

31. Use of trimlines smaller than 10% increases the relative waste of the water resource.

Hydrology and Water Development

32. Spring discharge is closely related to incidental recharge from surface water irrigation within the service area of the North Side Canal Company.

33. The sensitivity of spring discharge to incidental recharge is likely increased near the edges of the aquifer system near the Hagerman Rim and Rangen.

34. The Winter Water Savings Program of the North Side Canal Company alone may have reduced incidental discharge to the ESPA above the Thousand Springs reach by roughly 150,000 acre-feet per year beginning in 1961.

35. Conversion of irrigated lands from flood and furrow irrigation to sprinkler irrigation has significantly reduced incidental recharge.

36. Sprinkler usage under the North Side Canal Company grew from zero percent of the service area in 1982 to 100% of the service area by 2008.

37. Approximately 24,000 linear feet of lateral off the W-canal in the area west of Wendell, in proximity to Rangen, have been lined or placed in pipe since the 1990s, primarily to reduce excessive seepage losses, which are incidental recharge.

38. All of the foregoing reductions in incidental discharge are reductions in waste of water.

39. Prior to development of irrigation under the North Side Canal Company natural flow from springs in the Milner to King Hill reach was estimated to be about 4,000 cfs. Spring flows reached a peak at about 7,000 cfs in the early 1950s and have declined since that time. The average annual discharge for the 10-year period ending in 2011 is about 5,000 cfs, which is still above the natural (predevelopment) levels

40. When significant surface water irrigation began in the NSCC area the seasonal variability of spring discharges increased in addition to the magnitude of average annual flows. Prior to development, the pronounced seasonal pattern of spring flows that currently exists did not appear to exist.

41. Reductions in total annual spring discharge are also related to drought episodes.

Rangen Water Use

42. Discharges from the Curren Tunnel are divided between Rangen pipelines, three irrigation diversions, and spills to Billingsley Creek from the Rangen Box.

43. The North Snake Groundwater District has been providing mitigation supplies to the irrigation water users through the Sandy Pipeline since 2003. This pipeline is believed to have nearly eliminated irrigation diversions from the Curren Tunnel outlet.

44. Flows in Billingsley Creek are divertible by gravity to Rangen's large raceways but not to the hatch house, upper (small) raceways, or culinary use, all of which are presently supplied only by pipelines from the Tunnel.

45. Spills from the Rangen Box may remain in Billingsley Creek and bypass the Rangen facilities under some circumstances.

46. It is feasible to pump water from Billingsley Creek to Rangen's small raceways from the same point where Rangen diverts water into the large raceways. This would increase the efficiency of use of Rangen's existing physical supplies by making the total discharge of the Rangen complex available to all of Rangen's raceways.

ESPAM2.1 Model

47. Observations of ESPA geology suggest it is highly complex, comprised of overlapping fractured basalts interspersed with sedimentary formations, with hydraulic characteristics that can vary substantially over short distances.

48. ESPAM2.1 is, like all models, a simplified representation of reality, and this leads to model uncertainty.

49. ESPAM2.1 is comprised of cells that are one mile square.

50. Within each ESPAM2.1 grid cell, aquifer characteristics are assumed to be homogenous and isotropic.

51. This assumption of homogeneity means that hydrologic and geologic details of a scale smaller than the cell cannot be explicitly represented in the model.

52. Considerable amounts of pertinent input data are not known at even the one-square mile level of spatial resolution of the ESPAM2.1 grid.

53. ESPAM2.1 is comprised of a single layer of cells of uniform thickness.

54. ESPAM2.1 assumes constant thickness throughout the model domain and constant transmissivity within each cell. These assumptions may result in substantial misrepresentation of flow conditions in some parts of the aquifer, such as the Hagerman rim, where thinning occurs and preferential flow pathways become more restricted.

55. The discharges at Rangen are represented in ESPAM2.1 as a single drain.

56. This single-drain representation does not allow ESPAM2.1 to distinguish flows emanating from the Curren Tunnel from flows emanating from natural springs in the Rangen complex.

57. The generalizations and simplifications in ESPAM2.1 can introduce significant error into model results, particularly for highly localized conditions such as those governing discharge from specific outlets of a specific spring complex.

58. ESPAM2.1 has a large number of cells and each cell has a large number of adjustable parameters, so the total number of adjustable parameters in the ESPAM2.1 model is large.

59. The large number of parameters reflected in ESPAM2.1 increases the likelihood that the model is not unique.

60. ESPAM2.1 simulates conditions that are not physically possible and conditions that are in direct opposition to observed conditions in the real system. These discrepancies reveal serious model misrepresentation of detailed aquifer behaviour in the Rangen area, and raise doubt as to the accuracy of model predictions there.

61. Many of the conceptual aspects of ESPAM2.1 fail to reflect observed characteristics of the aquifer system in the Rangen area. These failures lead to conceptual uncertainty in the ESPAM2.1.

62. Each of the input data types used in ESPAM2.1 carries its own uncertainties that can stem from, among other things, the inability to measure a condition accurately (or at all) and from the spatial or temporal resolution of measurements.

ESPAM2.1 Calibration

63. Calibration uncertainty reflects the fact that many combinations of model parameter values may lead to equally well-calibrated models.

64. The ESPAM2.1 was calibrated under the assumption that aquifer transmissivity in any given cell is constant over the calibration period. This assumption has not been validated, and there are many locations and situations in the model domain and over the model calibration period where it is probably not true.

65. ESPAM2.1 was calibrated using an automated approach implemented in a computer program called PEST.

66. ESPAM2.1 systematically under-estimates discharge at the Rangen spring in the early years of the calibration period while over-estimating it in the later years.

67. ESPAM2.1 systematically under-predicts the water level at the closest well to Rangen that was used for calibration by 20 feet. ESPAM2.1 also consistently under-predicts the water level in another nearby well.

68. The under-prediction of water levels near Rangen is partly a result of the fact that discharge targets were weighted more heavily than water level targets in the calibration process.

69. Because predicted water levels are too low, PEST increased the drain conductance to values higher than are suggested by observation, thereby embodying in ESPAM2.1 a mischaracterization of the real physical relationship between water levels and flows at Rangen.

70. This mischaracterization results in over-sensitivity of the change in drain flow to a simulated change in water level due to curtailment. This over-sensitivity is carried into the superposition model used for curtailment, with the result that changes in spring flows are over-predicted by nearly a factor of 4.

71. The calibrated drain conductances in ESPAM2.1 range over 4 orders of magnitude. This extremely large variation suggests that the set of calibrated parameters is quite fragile and that PEST can readily find alternative parameter sets that provide acceptable calibrations.

72. ESPAM2.1 differs from ESPAM2 in the correction of an error that arose in the calculation of the water budget in the Mud Lake area and overestimated aquifer recharge by approximately 89,000 acre-feet/year in that area of the model domain. This represents a change of less than one percent in the overall water balance for the ESPA.

73. Correction of this error required re-calibration of the model, so a new set of model parameters, including drain conductances were developed. These are the parameters used in ESPAM2.1.

74. The drain conductances in ESPAM2.1 differ from those used in ESPAM2 by more than the 1% change in water budget associated with the correction. The conductance for the Rangen drain decreased by about 4%, but some drain conductances in the area changed by nearly 1000%. Some cell transmissivities in the area near Rangen changed by more than 100%.

75. These changes in conductance and transmissivity are carried directly into the superposition models used to calculate the flow changes resulting from curtailment.

76. The area encompassed by the 5% trimline is substantially larger with ESPAM2.1 compared to ESPAM2, and this expansion is mainly in areas on the opposite side of the Malad Gorge from Rangen, which are hydrogeologically disconnected from the Rangen spring.

77. Large changes in calibrated parameter values and model results suggest that ESPAM2 and ESPAM2.1 may be over-parameterized, and that other comparable calibration solutions easily can be reached with only minor perturbations in model assumptions.

Estimation of Benefits from Curtailment

78. ESPAM2.1 represents the Rangen spring as a drain and the flow in that drain as a linear function of water level in the cell that contains the drain.

79. Application of ESPAM2.1 to estimate changes in spring flow due to curtailment employs the method of superposition.

80. The principle of superposition relies on the assumption that the system being modeled and the model behaves in a completely linear way.

81. If the system being simulated or the model exhibits important non-linear behaviours, a superposition model can introduce significant error into the analysis of effects of stress changes.

82. Analysis of observed water levels and Range spring flows by Hinckley demonstrates that the relationship of Rangen flow to water levels in nearby wells is not linear.

83. The structure of the aquifer and conditions in the aquifer along the Hagerman Rim in the region of Rangen indicate that the behaviour of the aquifer in that region is not linear.

84. The large number of parameters reflected in ESPAM2.1 increases the likelihood that the model is not linear.

85. There are a total of 406 groundwater irrigated acres relying on rights junior to Rangen's 1962 priority within the 10% trimline, using 1,445 acre-feet of groundwater. At steady state, curtailment of pumping on these lands would cause total modeled flow at the Rangen springs to increase by 0.19 cfs (141 af/y assuming year around flow). Not all of this increase would accrue to the Martin-Curren Tunnel, but the ESPAM2.1 model does not represent flows in the tunnel. It would take somewhat less than a year for discharge to reach 90% of this modeled steady state increase.

86. There are a total of 565,023 groundwater irrigated acres within the model domain relying on rights junior to Rangen's1962 priority, using 1.46 million acre-feet (MAF) of groundwater. At steady state, ESPAM2 predicts that curtailment of pumping on these lands would cause modeled discharge at Rangen to increase by 18.07 cfs. It would take approximately 16 years for modeled discharge to reach 90% of this steady state increase.

87. Because the model domain, irrigated lands and water rights are the same in ESPAM2.1 as in ESPAM2, conclusion (86) above would also be expected to apply to results from ESPAM2.1.

2.0 WATER DEVELOPMENT AND USE ON THE EASTERN SNAKE PLAIN

2.1 Hydrology

The Snake River flows along the southern edge of the Eastern Snake River Plain (ESRP), a broad arcuate plain that covers an area of approximately 10,000 square miles in southeastern Idaho. As shown on Figure 2.1, the two main branches of the Snake River are the South Fork, which primarily drains the eastern side of the Teton mountain range, and the Henry's Fork, which primarily drains the western side of the Teton Range and joins the South Fork near Idaho Falls. Several smaller tributaries enter the Snake River from the south, the largest being Willow Creek and the Blackfoot, Portneuf and Raft rivers. With few exceptions, tributaries from the mountains to the north of the plain flow out onto the plain and recharge the underlying aquifer. Because of its porous surface, there are no significant surface water features on the plain itself.

At Milner Dam, northeast of Twin Falls, the Snake River drops into a canyon making gravity diversion of river flows impossible; large irrigation canals at Milner seasonally divert all but a small amount of the river flow. The canals diverting from the Snake River at Milner Dam, as well as others diverting from the lower Big and Little Wood Rivers, deliver large amounts of irrigation water to lands in Jerome, Gooding and Lincoln Counties above the north rim of the river canyon. The Snake River itself is largely restored by the time it reaches King Hill due to spring discharges from the north wall of the Snake River canyon and tributary streams such as Rock Creek, Salmon Falls Creek and the Malad River.

The ESRP is underlain by a vast basalt aquifer system, the Eastern Snake Plain Aquifer (ESPA), formed when intermittent lava flows filled ancestral valleys and canyons of the Snake River (Stearns and Crandall, 1938). In the central part of the ESPA, these and other formations extend to a depth of more than 3,000 feet (Whitehead, 1992). The total volume of water stored in the ESPA has been estimated to be as high as 1 billion acre-feet (IDEQ, 2006).

The agriculturally productive areas of the Plain occur in sedimentary and aeolian deposits overlying the most recent (Quaternary) basalts, which outcrop in numerous places. The porous and fractured basalt formations in the upper part of the ESPA can store and transmit large amounts of water and have been developed as a groundwater resource. Lindholm (1996) estimated that the upper 500 feet of the aquifer may contain 200-300 million acre-feet, an amount approximately 50 times greater than the combined surface water storage above King Hill.

Between Milner Dam and King Hill are numerous springs that emerge from the north side of the canyon and flow to the river. In some cases there are very well-defined outlets for these springs while in other cases they discharge through talus slopes and the actual outlets in the canyon wall can't be seen. There are also some springs that emerge in the river itself. This reach of the river is often referred to as the Thousand Springs Reach, though there is also an individual spring complex named Thousand Springs. A few of the larger spring complexes along the north wall of the canyon are at Crystal Springs, Clear Lakes, Box Canyon, Thousand Springs, Billingsley Creek and the Malad Gorge.

Figure 2.2 shows the annual average water budget for the period 1981-2008 used in development of the ESPAM2.1. Note that this is not a water budget for the ESPA, as it includes surface water supplies that are consumed directly without entering the aquifer. Based on Figure 2.1, average recharge to the aquifer system from precipitation on non-irrigated lands, from tributary underflow, and from non-Snake River seepage is 2.46 million acre-feet (MAF). This relatively small component of overall aquifer recharge is still greater than the total groundwater consumption simulated in curtailment to 1870 (Sukow, 2012) indicating that groundwater use remains less than the reasonably anticipated rate of future natural recharge.

2.2 North Side Canal Company

Early irrigation development on the ESRP was concentrated in the upper portions of the basin, above Blackfoot. Irrigation development in the lower portion of the plain began in 1877 with appropriations from the lower Big and Little Wood Rivers north of Wendell and Shoshone. By 1900, surface water rights totalling more than 900 cfs had begun operating to irrigate lands above the Malad Gorge (at their confluence, the Big and Little Wood Rivers become the Malad River).

Diversions from the Snake River onto the western ESPA began in 1905 with the development of the Twin Falls Project. Small diversions by the Twin Falls North Side Land & Water Company (predecessor to the North Side Canal Company) began in 1908. Diversions quickly grew from 250 thousand acre-feet (KAF) in 1909 to 1.2 million acre-feet (MAF) in 1912 (USGS, 1956). Considerable water was diverted in the first decade of canal operation to fill the Jerome Reservoir, but that project was abandoned in 1918 after it became clear that seepage losses from the reservoir would prevent it ever being filled (Crandall, 1923; USGS, 1956). North Side Canal Company (NSCC) diversions at Milner Dam have averaged about 986,000 af/y over the last 10 years. Present acreage served by the NSCC is reported to be 154,067 acres. Figure 2.3 shows the present service area and main canals and laterals of the NSCC.

For the first half of the 20th century, the NSCC diverted water in the winter as well as during the irrigation season. This was done primarily to provide domestic and stock water to small towns and farms. There is no significant crop water demand in the winter, so considerable amounts of the winter diversions undoubtedly recharged the ESPA in Jerome and Gooding Counties or were spilled over the canyon rim at the ends of laterals.

As part of its Regional Aquifer System Analysis (RASA) study, the USGS estimated that by 1952 more than 24 MAF of water had been added to the aquifer by incidental recharge from surface water irrigation (Kjelstrom, 1995). The importance of incidental recharge resulting from seepage losses from surface irrigation systems is evident in Figure 2.4a, b which is reproduced from the RASA study. Figure 2.4a shows the close correlation between incidental recharge and spring discharges in the Milner to King Hill reach of the river. The pattern of incidental recharge is clearly superimposed on a longer term increasing trend of spring discharge from 1912 to the mid-1950s, and is very closely related to the declining trend in spring discharge since the mid-1950s. Figure 2.4b shows the estimated change in ground water storage from this incidental recharge.

Figures 2.5 and 2.6 are from another RASA report (Goodell, 1988). Figure 2.5 shows the early 20th century increase in water levels in three observation wells, the locations of which are shown on Figure 2.6. Water levels in observation well 8S-17E-19BBB1 reflect water levels in the aquifer beneath the area irrigated by the North Side Canal Company. It can be seen that the aquifer water level in this area rose by approximately 45 feet between 1900 and 1950 as the result of incidental recharge from surface water irrigation.

Winter diversions all but ended in about 1960 as the Company participated in the Winter Water Savings Program, which sought to stop 435,000 af of "wasteful non-irrigation season diversions" and redirect this water to storage in Palisades and American Falls Reservoirs (USBR, 1946). The Palisades Winter Water Savings agreements went into operation in 1961 and generally required participating canal companies to cease diversions in the months of November through March. Figure 2.7 is derived from records of the USGS and the IDWR and shows the historical November through March diversions of the NSCC. The onset of the Winter Water Savings Program is clearly evident in this diversion record. Based on Figure 2.7, the Winter Water Savings of the North Side Canal Company alone may have reduced incidental recharge to the ESPA above the Thousand Springs reach by roughly 150,000 acre-feet per year (207 cfs).

Prior to the 1950s, flood and furrow irrigation was the primary method of water application on the ESRP. Kjelstrom (1995) notes that by the 1970s about 20 percent of surface water irrigation distribution systems had converted from gravity application methods to sprinkler application methods and that this conversion had reduced deep percolation to the aquifer. In 1981 the University of Idaho published (Hamilton, et al., 1981) the results of a survey of the responses of irrigators to the severe drought of 1977. Table 2.1 is reproduced from the Hamilton report. It shows that many irrigators on the ESRP had installed sprinkler systems, had added gated pipe, and had lined ditches as a result of the 1977 drought.

Information provided to the IDWR by the North Side Canal Company in connection with the 2005 delivery call of the Surface Water Coalition shows that in 2004 sprinklers were the primary method of water application on 88 percent of the North Side service area. Documentation for the current groundwater model of the Eastern Snake Plain Aquifer (ESPAM2.1) reflect a growth in sprinkler usage under the NSCC from 0% of the service area in 1982 to 100% by 2008. This has undoubtedly further reduced aquifer recharge in the area of the springs.

Figure 2.8 shows the portion of the NSCC service area generally between the town of Wendell and the head of Billingsley Creek. The irrigation laterals shown in this area are part of the W-lateral system. Lateral W-40 extends nearly to the head of Billingsley Creek, ultimately reaching a spill point on the canyon rim immediately to the north of the Rangen aquaculture facility. Recent data (Sullivan, 2012) show that flows into the lower portion of the W-lateral system, have declined about 20,000 af/y since the late 1980s. Interviews of NSCC personnel (Wertz, pers. comm., 2012) revealed that approximately 24,000 linear feet of laterals off the W-Canal in the area west of Wendell have been lined or placed in pipe since the 1990s, primarily to reduce excessive seepage losses.

The spill point at the end of W-40 was visited in June, 2012, and did not show evidence of current use. As with other canal companies in the area, the NSCC has been attempting in recent years to consolidate and reduce spills to the river for water quality management purposes. The primary spill point for the W-Canal system is now into the Malad Gorge just downstream of the State Park.

2.3 Springs in the Milner to King Hill Reach

As mentioned previously, between Milner Dam and King Hill the Snake River flows in a deep canyon. There are numerous springs discharging from the walls of this canyon, the majority of them being on the north side in an area known as the Thousand Springs reach, including an individual spring complex named Thousand Springs. In some cases there are very well-defined outlets for these springs while in other cases they discharge through talus slopes and the actual outlets in the canyon wall can't be seen. There are also some springs that emerge in the river itself. Figure 2.9 shows the locations of major spring complexes in the Milner to King Hill reach.

The earliest records of spring discharge measurements in this reach of the river date back to 1902. In the spring of that year the U.S. Department of Agriculture and the U.S. Geological Survey (USGS) separately made measurements on several of the springs in this reach of the river. These and other early measurements are summarized in Nace, et al., (1958). J.D. Stannard, the investigator for the Department of Agriculture estimated the total discharge of springs on both sides of the river between a point 3 miles above Twin Falls and a point 10 miles below the Malad River (roughly the entire Milner to King Hill reach) to be 3,833 cfs. These 1902 measurements were made before irrigation development under the North Side Canal system, though not before irrigation diversions began from the lower Wood River to supply lands north of Wendell and Shoshone. Kjelstrom (1995) estimated that the pre-irrigation (pre-1880) discharge of springs between Milner and King Hill averaged about 3.0 maf, or 4,140 cfs. Mundorff, et.al. (1964) estimated the natural discharge from the aquifer in the Thousand Springs Reach to be 4,000 cfs, and possibly less.

When significant surface water irrigation began in the North Side Canal area spring discharges changed, increasing in seasonal variability and in overall magnitude. Meinzer (1927) prepared an inventory and description of large springs in the United States, including the springs in the reach of the Snake River between Milner Dam and King Hill. Figure 2.10, reproduced from the Meinzer report, illustrates the close relationship he found between the combined spring discharges at the Blue Lakes and Clear Lakes spring complexes and the quantity of irrigation water applied to the Eastern Snake River Plain above the springs via the North Side Canal Company. Figure 2.10 shows that the monthly rise and fall pattern of North Side Canal diversion is followed, in a slightly delayed fashion, by a similar monthly pattern in spring discharge. Canal diversions were substantially smaller in 1919 (shortly after the Jerome Reservoir project was abandoned) than they were in the preceding two years, and the subsequent rise in spring discharge is also substantially smaller. A comparison of the two 1902 observations of flow at Blue Lakes given in Nace, one in April and one in August, showed almost equal flow rates. So the seasonal spring discharge pattern evident in the period 1917-1920 didn't appear to exist in 1902 at Blue Lakes and Clear Lakes, prior to major irrigation development above the springs. This emphasizes the importance of localized patterns of incidental recharge to flows of specific springs.

The IDWR prepares estimates of the annual spring discharge to the Thousand Springs Reach based on a method originally developed by Kjelstrom (1995b) and documented in USGS Water-Resources Investigation Report 95-4055. Figure 2.11 is a plot of the discharge estimates prepared by the IDWR for the period 1902-2011. The average of the annual discharge values for the 10-year period from 1902-1911 is 4,207 cfs. The average annual discharge for the 10-year period ending in 2011 is 5,019 cfs.

Also shown on Figure 2.11 is the annual value of the Palmer Drought Severity Index (PDSI) for NOAA Climate Zone 7 (NOAA Earth System Research Laboratory Physical Sciences Division 2012). The PDSI is a commonly used water supply index that incorporates precipitation, temperature, runoff and soil moisture conditions. Greater positive values of the PDSI reflect increasingly cooler and wetter conditions; greater negative values reflect increasingly warmer and drier conditions. A relationship can be seen in Figure 2.11 between drought episodes and reductions in total estimated spring discharge to the Milner to King Hill reach.

From the foregoing, it can be concluded that pre-development springs flows in the Thousand Springs Reach were probably not greater than 4100 cfs; that flows peaked in the early 1950s at approximately 6900 cfs primarily as a result of surface water irrigation development; and that flows have declined to current levels as a result of changes in surface water irrigation practices, drought and groundwater development. However, spring discharge between Milner and King Hill remains above natural (predevelopment) levels.

2.4 Groundwater Development

With the exception of shallow wells constructed in the Mud Lake area in the 1920s, ground water development of the ESPA did not begin in earnest until the late 1940s. The first project relying heavily on ground water supplies was the Minidoka North Side Pumping Division of the Minidoka Project (now the A&B Irrigation District) which began operation in 1948. While the majority of the subsequent permits were for irrigation of new lands, many were for supplemental irrigation of lands already irrigated with surface water supplies. In addition, the benefits of sprinkler irrigation have led to the conversion of some formerly surface-water irrigated lands to ground water use. Ground water development began to level off in the 1980s and a moratorium on new irrigation well development has been in place since 1992.

Farms in the Wendell area were initially supplied with irrigation water by the NSCC (Sullivan, 2012). Conversion of irrigated lands from surface to groundwater sources and development of new groundwater-supplied lands in the area began in the 1950s. Figure 2.12 shows the growth in groundwater permits in the area from 1948 until 1992, when a moratorium on further groundwater irrigation permitting went into effect. Notable increases in permitting occurred in 1960-61, just prior to Rangen's application for water right 36-2551, and in 1973-76, just prior to Rangen's application for water right 36-7469. Figure 2.13 shows the current Points of Diversion for groundwater rights in the area between Wendell and the head of Billingsley Creek; these points are color-coded to show their priorities relative to July 13, 1962.

Sullivan estimates that there were approximately 25,000 acres of irrigated land under the W Canal in 1953 and about 30,500 acres in 2009. In 1953 there was little or no groundwater irrigation under the W Canal. By 2009 roughly 10,000 of the formerly surface-water irrigated acres were supplied in whole or in part with groundwater and about 9,300 acres of new acreage was being served by groundwater (about 3,500 acres of surface water irrigation had been retired). Given the 1992 moratorium on new groundwater irrigation, it is reasonable to assume that nearly all of this groundwater use was actually in place by 1992.

Figure 2.14 shows observed groundwater levels in two wells in the area between Wendell and Rangen. Records of groundwater levels are less complete as one goes back in time, so the wells shown in Figure 2.14 do not illuminate aquifer conditions in earlier periods. It can be seen from Figure 2.14 that that seasonal fluctuations in water levels are about 5 feet in this area, with lows generally occurring in the months of March (well 992) and July (well 989). Annually, water levels have declined somewhat since 1985, with levels appearing more stable in the last 10 years. These declines are likely due to changes in surface water irrigation practices, including spill management, lining or piping of laterals, and conversions from surface to groundwater use, to drought, and to that increment of groundwater pumping brought online since 1985.

3.0 RANGEN SPRINGS DEVELOPMENT AND USE

3.1 Billingsley Creek Overview

Billingsley Creek enters the Snake River northwest of the town of Hagerman, just upstream from Lower Salmon Falls Dam. The creek is fed by a series of springs emanating from the Quaternary basalts forming the canyon rim in western Gooding County. Figure 3.1 is an aerial photo of the area showing the creek and the locations of selected spring discharge points. Figure 3.2 shows the measured flows of Billingsley Creek at the USGS gaging station (13134600) at the Highway 30 bridge just north of Hagerman. Records at this station are not continuous, and spring and creek flows are diverted both above and below the station for aquaculture, irrigation and other uses.

The Martin-Curren (aka Curran, Kearn) Tunnel and Rangen aquaculture facility are located at the upper end of Billingsley Creek. Figure 3.3 is an aerial photo of the Rangen facility showing key features of the area that will be referred to later in this section. Flows from the Tunnel and from other spring outlets and seeps in the Rangen area form the headwaters of Billingsley Creek.

The Rangen facility was constructed in 1962, apparently expanding on an earlier, smaller aquaculture operation purchased by Rangen in May of that year (Twin Falls Times-News, December 30, 1962). The facility was launched as a research center focused on trout diseases and diet, and on hatchery management problems.

The primary physical sources of water used at the Rangen facility are the Martin-Curren Tunnel and natural springs, most of which emerge from the talus slope about 45 feet in elevation below the tunnel portal (Farmer, 2009). Water from the Tunnel is divided between Rangen pipelines and three irrigation diversions. The natural springs all discharge to Billingsley Creek. Flows in Billingsley Creek are divertible by gravity to Rangen's large raceways but not to the hatch house, upper raceways, or culinary use, all of which are presently supplied only by pipelines from the Tunnel. Inspection of the Rangen facilities by IDWR personnel in 2003 concluded that some spring inflow to Billingsley Creek also occurs below the diversion for the large raceways (Berkey, 2003a).

3.2 Water Rights

Water rights for flows in the headwaters of Billingsley Creek in the area of the Rangen facility are listed in Table 3.1. The earliest rights date to 1884 and are for irrigation and domestic use.

The earliest right for fish propagation is Rangen's 1957 priority for 1.46 cubic feet per second (cfs). This may have been the primary water right for Rangen's predecessor. The present delivery call seeks administration of groundwater rights junior to Rangen's 1962 priority (36-2551), which is sourced by the Snake River Basin Adjudication (SRBA) Court at the Martin-Curren Tunnel.

The irrigation rights of Candy, Morris and Musser are also sourced at the Martin-Curren Tunnel. These diversions provide water to irrigate parcels south of Billingsley Creek. The water rights for these diversions are senior to the Rangen rights, dating to as early as 1884. Because the irrigation diversions are consumptive with respect to Billingsley Creek, they reduce the water supply available to Rangen from the Tunnel.

In 2003, anticipating that groundwater users might in the future be required to mitigate declines in Tunnel and spring flows, the North Snake Groundwater District (NSGWD) voluntarily constructed a pipeline (the "Sandy Pipeline") from ponds in Section 5 of T8S, R14E (the "Sandy Ponds") to the Curren Ditch. The pipeline was constructed so that it could also supply irrigation water to Candy, Morris and Musser, thereby reducing or eliminating those irrigation diversions at the Tunnel and increasing the Tunnel supply available for Rangen. This pipeline is in operation and is believed to have nearly eliminated irrigation diversions from the Tunnel outlet.

The Curren Ditch diverts from the creek below the Rangen facility under irrigation rights that are also senior to the Rangen aquaculture rights. However, since Rangen's aquaculture use is non-consumptive, the Curren Ditch does not call for bypass of Rangen's more junior aquaculture rights.

Groundwater development on the plain above the Curren Tunnel began in the early 1950's. Figure 2.12 showed the evolution of groundwater rights in the area east of Billingsley Creek. The earliest groundwater rights in the immediate area date to 1952. Notable increases in permitted acreage occurred in 1959-61 and in 1973-76, just prior to Rangen's applications for water rights 36-2551 and 36-7694. By the time of Rangen's 1962 water right, about 3900 acres had been permitted. At the time of Rangen's 1977 water right, about 8300 acres had been permitted. By 1992, when the moratorium on new groundwater irrigation went into effect, permits for about 10,000 acres had been issued.

3.3 Curren Tunnel Development

The Curren Tunnel is excavated into the canyon rim above the Rangen facility. It extends roughly 100-300 ft into the basalt forming the rim (Tate deposition testimony, 2012), at a depth roughly 70 feet below the ground surface above the rim (Hinckley, 2012). The tunnel is bifurcated some distance into the cliff into north and east forks. Water flows out of the Tunnel by gravity.

It appears that the Tunnel excavation had at least commenced by October of 1884 (New International Mortgage, 1932) with the aim to deliver irrigation water via a ditch (i.e., by gravity) to lands on the bench area south of Rangen. A feature article in the December 30, 1962, Twin Falls Times-News describes the source of Rangen's supply as "man-made springs on the north side of the canyon" where "early pioneers in search of irrigation water drilled a hole into the cliff and struck water." USGS Water Supply Paper 1463 (Nace, et.al., 1958) contains a Billingsley Creek flow observation made in April, 1902, with remarks that "Water emerges from a tunnel dug into brecciated, highly permeable basalt, and from the talus slope below the tunnel…" The 1932 decree from New International Mortgage Bank v Idaho Power Company, et.al., an adjudication of

water rights in Billingsley and Riley Creeks, grants 1884 priority rights to water "…developed and diverted…by means of a tunnel commonly known as the Curran Tunnel…".

According to Idaho Code 42-230(b) a "well" is defined as "an artificial excavation or opening in the ground more than eighteen (18) feet in vertical depth below land surface by which groundwater of any temperature is sought or obtained." Based on the foregoing descriptions of its development, the Curren Tunnel appears to meet this definition.

About the first 50 feet of the Tunnel is lined with large diameter corrugated steel pipe; beyond this the tunnel is unlined. It is not known when the corrugated steel lining was installed. A 6" diameter PVC pipe is laid along the bottom of the steel pipe, extending beyond it into the unlined portion to the bifurcation. This PVC pipe carries water for laboratory, culinary and landscape irrigation use at the Rangen facility. Based on a diagram produced by Rangen (RANGEN001907), it is believed that this PVC pipe was installed in 1976.

The PVC pipe does not carry all the water emerging from the Tunnel. The remainder of tunnel discharge is collected in a concrete division box (the "Farmers box") at the mouth of the tunnel, shown in Figure 3.4. The Candy, Morris and Musser pipelines deliver water from this division box to parcels south of the Rangen facility; the elevation of the Tunnel outlet allows this irrigation delivery to operate by gravity.

Two Rangen pipelines also take water from the Farmers box and water can spill from the box. The two Rangen pipelines flow into another concrete box, the "Rangen box" shown in Figure 3.5, which is further down the slope toward the Rangen facility. There they enter the pipeline serving the hatch house and research facility. Spills from the Rangen box, as well as flows from other spring outlets, flow into Billingsley Creek and can be diverted into Rangen's large raceways.

There are other spring outlets in the vicinity that also supply water to the Rangen facility. The largest of these emerges about 45 ft below the Curren Tunnel and flows to Billingsley Creek. Based on recent discharge records, discussed in more detail below, these "lower" springs produce roughly twice the flow of the Tunnel.

3.4 Discharge Records

The earliest record of discharge from springs in the Rangen area is contained in Nace (1958). Table 27 in that report shows a Billingsley Creek flow of 54.3 cfs in April, 1902, at a location where Road E2900S (aka Hagerman Highway) crosses Billingsley Creek. This observation post-dates the excavation of the Tunnel, and potentially includes discharges from other springs in the area. Other than a few subsequent measurements in the general vicinity, systematic recording of spring discharge in the area did not begin until the Rangen facility was operating.

The only measurement of discharge specifically from the Curren Tunnel was in the period between 1993 and 2009 when the IDWR operated a sonic measuring device inside the tunnel. This measured the portion of tunnel flow not conveyed in the 6" PVC pipe installed in the tunnel

by Rangen. All other historical measurements of spring discharge are derived from measurements made by Rangen at locations within the hatchery or on Billingsley Creek.

Flow measurement within the Rangen facility relies primarily on recording the depth of water flowing over the check dams in the "large" and "CTR" raceways, and depth of water flowing over the "lodge dam" in Billingsley Creek shown in Figure 3.6. Flow depth is apparently measured by a metal ruler placed on the crest of the dams as shown in Figure 3.7 (Exhibit 7a from Rangen 1st Request; Yenter, 2003). It appears that the flow from the CTR raceways reflects flow through the Rangen hatchery and, when combined with discharge over the lodge dam and diversions for irrigation, gives the total discharge of the spring complex.

Along with most other spring users, Rangen began submitting diversion records to the IDWR in 1995. In late 2003, responding to a request from IDWR Director Karl Dreher, Rangen submitted monthly flow records covering the period 1966-2003. These data, and the measurement methods used by Rangen, were subsequently reviewed by IDWR technical staff (Yenter, 2003; Berkey, 2003, 2003a). This review included field inspection of measurement sites and methods, and verification of various estimates used by Rangen in its flow summarization. The inspection concluded, among other things, that the flow record reflected total spring complex discharge rather than Rangen diversions and found that Rangen's flow measurement methods could underestimate the total discharge by 10-12%.

Figure 3.8 shows the IDWR records of total discharge from the Rangen complex, as well as observed flows from the Curren Tunnel and IDWR records for flow in the 6" PVC pipe from the Tunnel. Seasonal variability of flow is plainly evident as are longer term wet and dry spells. In the period of overlap between total flow and Tunnel flow records, it appears the Tunnel flow is the greater source of this seasonal variability. This is to be expected as the Tunnel penetrates the aquifer at a higher elevation than that of the natural springs. In his May 19, 2005, Order, former Director Dreher found decreases in the springs supplying the Rangen hatchery facilities to be correlated with repairs made to the facilities of the North Side Canal Company to reduce losses of surface water to ground water from the canal company's facilities above those springs in 1987, 1998, and 2000 (Order, FF 23). The 1992 moratorium on new irrigation wells suggests that decreases in discharge after the mid-1990's are not the result of groundwater pumping.

Figure 3.9 shows a regression analysis of total Rangen flow against observed Curren Tunnel flow. It can be seen that the relative contribution of the Tunnel is somewhat greater at higher total flow; this is to be expected from the relative elevations of the Tunnel and the natural springs that contribute to the total flow. At lower flow levels, the Tunnel may represent as little as 20% of the total Rangen flow. Over the last 10 years, the Tunnel discharge has represented roughly one-third of the total Rangen flow.

The regression shown in Figure 3.9 was used to generate estimates of Curren Tunnel flow for the entire period of record for Rangen total flow. The results of this procedure are shown on Figure 3.10, which plots both the monthly total Rangen flow and the monthly Curren Tunnel flow for the period 1966 through 2012. Also shown on Figure 3.10 are the cumulative water rights sourced at the Martin-Curren Tunnel by the Snake River Basin Adjudication (SRBA). The cumulative rights

at the Tunnel were 61.29 cfs prior to Rangen's April, 1977, appropriation. With that appropriation, cumulative rights at the Tunnel rose to 87.29 cfs.

It can be seen from Figure 3.10 that the flows from the Martin-Curren Tunnel have never been high enough to fully satisfy Rangen's 1962 priority (36-2551) and have never been high enough to provide any water to Rangen's 1977 priority (36-7694). Accordingly, it can be concluded that water was not available to water right 36-7694 at the time of its appropriation nor at any later time.

In his May 19, 2005, Order former Director Dreher found that the Department of Water Resources erred in licensing water right 36-7694 and should not have recommended it in the SRBA, because water was not available to it either at the time of its appropriation or subsequently (Order, FF 62, 63, 72). The foregoing analysis of Rangen discharge records shown in Figure 3.10 supports this conclusion.

Director Dreher also found that curtailment of water rights junior to July 13, 1962 (Rangen water right 36-2551) would "not at any time result in a meaningful increase in the quantity of water discharging from springs in the Thousand Springs to Malad Gorge reach of the Snake River, which includes the Curran Springs from which Rangen diverts surface water." (Order, FF 84). In its disclosure of June 12, 2012, the Department produced modeling results, apparently related to this finding, showing an analysis by Allan Wylie with a conclusion that Rangen could "at best expect" an increase of 0.22 cfs from curtailment.

A decomposition and back-casting of the historical monthly total discharge of the Rangen spring complex was also undertaken by Brannon (2009) apparently in anticipation of its use as a target for groundwater model calibration. This decomposition relied on Rangen measurements dating back to 1966. Figure 3.11 shows the results of this effort. Documentation of this work has not been provided by Rangen, though notes in the spreadsheet file submitted by Brannon to the IDWR allude to such documentation (Rangen Water History for IDWR.xls). Inspection of this decomposition supports the preceding conclusions that there has never been water available to water right 36-7694 since its time of appropriation.

While flows diverted from the Martin-Curren Tunnel can be delivered through the small raceways and reused in the large raceways, spring flows emerging below the Tunnel cannot. Based on a reconnaissance-level analysis (Coleman, 2012), it is feasible to pump water from Billingsley Creek to the small raceways from the same point where the diversion to the large raceways is made. This would increase the efficiency of use of Rangen's existing physical supplies by making the total discharge of the Rangen complex available to all of Rangen's raceways.

4.0 MODEL DEVELOPMENT

4.1 Background

The Enhanced Snake Plain Aquifer Model (ESPAM) is the current incarnation of numerical modeling of the Eastern Snake Plain Aquifer (ESPA) that began in 1974 (deSonneville, 1974). The ESPAM was created with review and input from the Eastern Snake Hydrologic Modeling Committee (ESHMC). The ESHMC is comprised of professionals working on water issues on the eastern Snake River Plain. Regular members include agency representatives (Idaho Department of Water Resources, U.S. Bureau of Reclamation, U.S. Geological Survey, U.S. Fish and Wildlife Service), industry representatives (Idaho Power), researchers (University of Idaho, Idaho Water Resources Research Institute) and private consultants representing various water user interests. While a diversity of interests are represented on the ESHMC, the committee is constituted by request and invitation and not through election or appointment on the basis of population, water right amounts, irrigated acreage, or other such factors. Committee decisions are generally reached by consensus, though this is not always possible to achieve.

Actual development of ESPAM was carried out by the IDWR and the Idaho Water Resources Research Institute (IWRRI). Model design, construction and calibration were reviewed and in some instances redirected by the ESHMC.

From the outset of the ESPAM modeling effort, it was recognized that there would be a need for future enhancements to the model as new information and modeling approaches became available. ESPAM Version 1.0 (ESPAM1.0) was released in 2004, followed shortly by ESPAM1.1 which corrected an input data error. Discussions regarding the scope of future enhancements to ESPAM1.1 began shortly after its release (e.g., Brendecke, 2009a). ESPAM2.0 was released in the summer of 2012; correction of an input data error has recently resulted in the distribution of ESPAM2.1.

4.2 Model Structure

4.2.1 Overview

Like its predecessors, the ESPAM2.1 is developed in MODFLOW, a groundwater modeling environment developed by the U.S. Geological Survey (McDonald and Harbaugh, 1988; 2000). In MODFLOW, aquifers are represented as a collection of rectilinear elements or “cells”. The MODFLOW code solves the equations of flow between these cells to determine how the aquifer will respond to changes in inputs or outputs. Figure 4.1 shows the grid of model cells used for ESPAM2.1.

Within each cell, aquifer characteristics (e.g., porosity, hydraulic conductivity) are assumed to be homogenous (the same throughout the cell) and isotropic (allowing flow to occur in all directions with equal ease) as would be the case if the cell were filled with clean sand of uniform grain size. This assumption of homogeneity means that hydrologic and geologic details of a scale smaller

than the cell cannot be explicitly represented in the model. MODFLOW has the capability to represent anisotropy (where flow occurs in preferential directions), but this feature has not been used in any versions of the ESPAM.

A MODFLOW model may be comprised of one or more vertical layers of cells. Multiple layers are typically used when there is more than one geologic layer that is meaningful to groundwater flow patterns. The thickness of cells in model layers can vary to reflect changes in thickness of subsurface formations, such as the thinning of water bearing formations that often occurs at the edges of aquifers.

Boundary conditions must be defined to characterize the patterns of flow into and out of the model domain, and MODFLOW provides a variety of special cell types for this purpose. River cells are used to represent subsurface flow between river reaches and the aquifer. Drain cells are used to represent aquifer discharge through springs. Constant flux cells are used to represent fixed amounts and patterns of subsurface flow into the aquifer from tributary valleys. Other special-purpose cells serve other functions.

Most of the cells in a MODFLOW model are general purpose cells. It is in these model cells that aquifer recharge from precipitation and irrigation, and aquifer withdrawals by pumping and evapotranspiration, among other things, are represented. To carry out a groundwater flow simulation, it is first necessary to develop a water budget of aquifer inflows and outflows at each model cell and to develop, through calibration, estimates of parameters representing the aquifer characteristics at each cell.

4.2.2 General Structure of ESPAM2.1

Like its predecessors, the ESPAM2.1 is comprised of cells that are one mile square. This means that features having dimensions smaller than one mile cannot be explicitly represented in the model. However, considerable amounts of pertinent input data are not known at even this one-square mile level of spatial resolution. For example, subsurface geology on the ESPA is known with certainty only at outcrops or at locations where drilling logs are available. Crop distribution information on the ESPA is available only at a county level from annual agricultural statistics based on self-reported data. Detailed water distribution to lands within canal companies can be quite variable as shares are transferred between users; even if this information were readily available it is difficult to embody in model inputs. As a result of these latter data limitations, crop distributions in ESPAM2.1 are assumed to be uniform county-wide, and surface water distribution is assumed to be uniform across every parcel of served land within groups of canal companies.

The resolution of input data may not present a problem when doing a regional-scale analysis because local errors, if random, may effectively cancel each other in the larger context. However, the questions presented in the present delivery call are quite localized in nature and this “error cancelling” cannot simply be assumed to occur. Hinckley (2012) has illustrated some of the discrepancies that exist between the coarse simplifications of ESPAM2.1 and the details of Rangen-area hydrogeology.

Like its predecessors, ESPAM2.1 is comprised of a single layer of cells of uniform thickness. This means that substantial aquifer thinning, such as occurs in the Hagerman-Wendell, Burley-Pocatello, and Rigby Fan-Mud Lake areas (Whitehead, 1992), is not represented in the model. This is important because aquifer transmissivity (T) is a linear function of the hydraulic conductivity of the aquifer material (K) and the aquifer saturated thickness (b), as shown in the following equation:

$T = Kb$

As the aquifer material (in this case the Quaternary basalt) thins, the transmissivity is reduced and resistance to groundwater flow increases. Saturated thickness is also reduced by drawdown of the water table, e.g., by pumping or by spring discharge, resulting in a non-linear relationship between water level and flow. The ESPAM2.1 assumes constant transmissivity throughout the model domain. This assumption is made largely for reasons of computational convenience, as will be discussed later in this report, but may result in substantial misrepresentation of flow conditions in some parts of the aquifer, such as the Hagerman rim, where thinning occurs and preferential flow pathways become more restricted.

Like its predecessors, the ESPAM2.1 represents springs using special-purpose drain cells. As shown in Figure 4.2, discharge from a drain cell is a function of the difference in head (Δh) between the computed water level in the cell and the assumed elevation of the drain outlet, and a conductance parameter (C) that effectively acts as a throttle on the rate of discharge. The conductance parameter can be expressed in units of cubic feet per second (cfs) per foot of head difference. While it is a calibrated value in ESPAM2.1 (calibration is discussed in a later section), under certain conditions it can be estimated from field observations.

Like its predecessors, the ESPAM2.1 uses data from a variety of sources to represent the water budgets of the aquifer and of individual model cells. These data include precipitation, surface water diversions, subsurface inflows from tributary basins, stream gage records, county surveys of crop distributions, estimates of evapo-transpiration (ET), methods of irrigation water application, and assumptions about irrigation canal seepage, among others. With few exceptions, the data sources used in the ESPAM2.1 are the same as those used in its predecessors.

From the foregoing, it can be seen that the ESPAM2.1 should not be viewed as a new model of the ESPA but as a relatively modest refinement of earlier versions of ESPAM. It has the same conceptual formulation as its predecessors and relies on the same data sources as its predecessors. Its spatial resolution is the same as that of its predecessors. Like its predecessors it "…is a regional-scale model … best applied for regional-scale predictions." (IDWR, 2012).

4.2.3 Key Differences between ESPAM2.1 and Its Predecessors

The ESPAM2.1 utilizes a longer study period (1980-2008) than did ESPAM1.1 (1980-2002). The addition of six years to the study period means that more input data are used in the ESPAM2.1,

though the basic data sources used remain the same in both models. The ESPAM2.1 utilizes monthly stress periods where ESPAM1.1 used semi-annual stress periods; the increased number of stress periods also increased the amount of input data used in ESPAM2.1, since each formerly semi-annual data value was replaced with 6 monthly values. In some cases (e.g., precipitation, canal diversions) this allowed more accurate temporal representation of water budget terms, while in others (e.g., tributary underflow) it required further disaggregation of data for which only annual estimates are available.

Surface water conveyance and application efficiency are represented in more detail in the ESPAM2.1 than in ESPAM1.1. A greater number of leaky canals were explicitly represented in ESPAM2.1 (primarily in eastern portions of the plain), though canal seepage losses are still considered to be constant throughout the model study period. Farm irrigation efficiency is assumed to increase somewhat in water-short years in ESPAM2.1 through an "On-Farm Algorithm" that operates on model input data. Irrigated acreage is slightly higher in ESPAM2.1 due primarily to the use of better image processing methods than were used for ESPAM1.1 (Sukow, 2012).

The ESPAM2.1 is calibrated to a larger number of spring complexes in the Milner-King Hill reach of the Snake River than was ESPAM1.1. This stems largely from efforts to develop more complete data sets of spring discharges than were available for ESPAM1.1. In large part, these data sets are based on diversion and flow measurements reported by spring users, with extrapolation to fill missing data. The data sets were then used as targets for calibration of drain cells representing those spring complexes. Some spring complexes in ESPAM2.1 are represented by using two drains within the same model cell; in general, this was done to encompass the range of observed outlet elevations of springs falling within the cell, but in some cases the springs so represented may have little hydro-geologic relation to one another. Figure 4.3 shows the distribution of drain cells used to represent springs in the ESPAM2.1.

The more comprehensive representation of spring complexes in ESPAM2.1 necessitated the use of General Head Boundary (GHB) cells to represent observed river gains that were not accounted for in spring discharge data (Wylie, 2012 memo). These unaccounted for flows were implicit in ESPAM1.1 spring discharges. GHB cells work in a fashion similar to drain cells in that their discharge is a function of head difference and a calibrated conductance parameter. Figure 4.3 also shows the distribution of these GHB cells, some of which occur in cells already containing drains representing springs.

4.3 Rangen Area Representation in ESPAM2.1

While all the refinements made in ESPAM2.1 have some effect on simulated flows and impacts at the Rangen springs, two refinements bear directly on them. The first of these is the use of the Rangen springs as a specific calibration target in ESPAM2.1. Figure 4.4 shows a close-up of the ESPAM2.1 model grid in the area of the Rangen complex. In ESPAM1.1, flows at the Rangen springs were estimated as a percentage of overall spring discharge to the Thousand Springs - Malad subreach (the cells that comprised this reach are highlighted on Figure 4.4). In ESPAM2.1, historical diversions and Billingsley Creek flow measurements reported to the IDWR

by Rangen were used to derive estimates of monthly total discharge that were used as a calibration target. The discharges at Rangen are represented in ESPAM2.1 as a single drain, though discharges actually occur at multiple outlets. This single drain representation does not allow ESPAM2.1 to distinguish flows emanating from the Curren Tunnel from flows emanating from natural springs in the Rangen complex.

The second ESPAM2.1 refinement of particular consequence in the Rangen area is the elimination of the Hagerman Valley from the model domain. This was done at the recommendation of geologist Dennis Ralston, who studied the area and reported to the ESHMC that the Tertiary formations underlying the Valley were not connected to the ESPA (Ralston, 2008)[1]. As a result, the canyon rim became the westernmost extent of the model domain in the Hagerman area in ESPAM2.1. Figure 4.5 shows the changes in the model domain made with ESPAM2.1, highlighting the change in the Rangen area.

Later, after comparing the historical discharges of springs used for calibration targets with reach gains computed from river gages, it was discovered that the observed reach gains substantially exceeded, by roughly 25%, the sum of spring discharges used as calibration targets (Wylie, 2011; 2012 memo). To remedy this discrepancy, GHBs were defined through several reaches to account for the undocumented gains, or "baseflows." This at least partially undid the change in model domain, as the baseflows from the ESPA are now assumed to pass through Ralston's "unconnected formations" to reach the Snake River. As will be discussed later, this results in simulation of unrealistic groundwater flow patterns in the Rangen area.

4.4 Model Calibration Process

4.4.1 General Approach

After conceptual formulation and data development, the next step in groundwater model development is calibration. Calibration is a form of "history matching" wherein initial values of model parameters (such as transmissivity) are adjusted to achieve a better correspondence between historical targets (e.g., measured water levels and spring flows) and model-predictions. Ordinary least-squares regression may be the most familiar example of this process; in it, the parameters of the regression equation (slope, intercept) are adjusted to minimize the sum of the squared differences between the regression line and the data observations. In this context, the groundwater model can be viewed conceptually as a regression equation.

Because of the many parameters that must be adjusted (several for each model cell), groundwater model calibration is often done using special software programs that solve this "inverse problem", so called because its aim is to use observed behaviors to specify the model rather than to use the model to describe the behaviors. The software program used to calibrate

[1] In his mapping of the geohydrologic framework of the Eastern Snake River Plain, Whitehead (1992) also excluded the Hagerman Valley from the Quaternary basalt aquifer system.

all versions of ESPAM has been the model-independent Parameter ESTimation program (PEST) developed by John Doherty (Watermark, 2005).

To find the "best" solution to the inverse problem, PEST seeks to minimize an objective function that reflects the overall sum of squared differences (or "residuals") between historical aquifer observations, or "calibration targets", and model predictions. The ultimate goal of calibration is to determine the set of parameter values that produce the smallest overall value of this objective function. Historical calibration targets included observed aquifer water levels, reach gains and spring discharges over the period 1980-2008, though not all targets had continuous data over this period. While PEST produces quantitative measures of calibration success, it is ultimately a matter of judgement for the modeller to decide that a given calibration is "good enough" for the purpose at hand.

The objective function used in model calibration effectively aggregates, using weighting and indexing assumptions, all the residuals in the model calibration data set down to a single number. The weighting assumptions used in ESPAM2.1 calibration were based on judgement. Because the objective function is a single number, it is normal for PEST to identify a parameter set that provides a closer calibration to some targets than to others. As the desired use of the model focuses on ever more detailed locations and time periods, it becomes more and more important to examine calibration success in specific areas of the model.

While the calibration of models with large numbers of parameters (such as ESPAM2.1) allows consideration of more factors affecting aquifer conditions, it increases the risk that any given PEST solution (i.e., an "optimal" set of parameter values) is not unique (Watermark, 2005). This means that there may be many other combinations of parameter values could produce a similarly minimized value of overall model error. This non-uniqueness creates one dimension of overall model uncertainty, which is discussed in more detail in a later section.

4.4.2 Calibration of ESPAM2.1

The parameters that PEST was allowed to adjust in ESPAM2.1 included conventional aquifer parameters such as transmissivity, specific yield, and streambed, drain and GHB conductances. In addition, PEST was allowed to manipulate a number of terms in the aquifer water budget where precise values could not be known. For example, PEST was allowed to adjust tributary inflow estimates and surface water irrigation efficiency assumptions, among other things. Given the large number of active cells in the model and the many aquifer water budget terms considered at each cell, the number of adjustable parameters in ESPAM2.1 calibration is large.

Doherty (Watermark, 2005) cautions that "…increased parameterisation normally results in increased parameter non-uniqueness at the same time as any semblance of model linearity rapidly fades from view." As will be discussed later in this report, the assumption of linearity is fundamental to both IDWR and Rangen efforts to quantify the flow changes resulting from curtailment. The large number of parameters reflected in ESPAM2.1 increases the likelihood that the model is not linear.

Reach gain and spring discharge targets were given greater weight in the calibration of ESPAM2.1 due to the fact that there were a far greater number of calibration target values for aquifer water levels than there were for these discharges. Without preferential weighting, PEST would try to match all targets with similar accuracy, by default placing more emphasis on aquifer water level targets. The weighting applied to targets essentially determines the degree to which PEST "focuses" its effort on minimizing error in certain types of model behavior. PEST provides guidelines for such weighting, but it ultimately becomes a decision made by the modeller.

The ESPAM2.1 was calibrated under the assumption that aquifer transmissivity in any given cell is constant over the calibration period. This assumption is computationally convenient in part because it avoids iterative recalculation of transmissivity as simulated water levels change, but it can lead to overestimation of transmissivity in some areas of the model domain (Johnson, et.al., 2010). A common rule of thumb in determining whether this assumption is justified is that simulated changes in water level should not be greater than 10% of overall saturated thickness (Reilly, et al, 1987). Areas where this condition is most likely not to be met are those where the aquifer is thinnest, such as at its edges, as is the case in the present delivery call. Hinckley (2012) estimates that the saturated thickness of the ESPA in the vicinity of Rangen is on the order of 50 feet. Water level changes in wells near Rangen are on the order of 5 feet, making the assumption of constant transmissivity (and the convenient assumption of linearity that it allows) questionable. Compounding this is the fact that fractures and heterogeneities of a scale much smaller than one mile likely dominate flow hydraulics at the thin edges of the aquifer.

4.5 Calibration Results

Calibration success can be assessed in several ways besides the final objective function value produced by PEST, which is not by itself informative. The most commonly used methods for assessing calibration are visual and mathematical comparisons of simulated values and their corresponding targets. It is also useful to examine simulated and observed flow regimes to assess whether model performance reflects general observations and geological constraints that might not be represented explicitly.

4.5.1 Comparison with Calibration Targets in Rangen Area

Figure 4.6 shows the calibrated and target discharge for the Rangen spring complex from the ESPAM2.1 final calibration, along with other representations of calibration fit. In general, the broader patterns of observed discharge are reflected in the modeled values; multi-year cycles and trends are apparent in both, as are seasonal variations. However, the ESPAM2.1 systematically under-estimates discharge in the early years of the calibration period while over-estimating it in the later years.

This systematic error is more apparent by the analysis of residuals that is also shown in Figure 4.6. This analysis shows the error in monthly simulation relative to mean discharge. If simulation errors are random, this plot of residuals should vary randomly about the zero line over time. In fact, Figure 4.6 shows that that ESPAM2.1 consistently under-predicts (by as much as 15 cfs) the total flows from the Rangen complex in the early part of the calibration period and consistently

over-predicts (by as much as 15 cfs) these flows in the more recent part of the period. Since similar patterns are evident at other target springs in the area it raises the prospect of a more general problem with ESPAM2.1 representation of springs in the Hagerman area and suggests that curtailment analyses, which look forward from present conditions, may over-predict increases in spring discharge from curtailment.

Figure 4.7 shows a comparison between simulated and target water levels in calibration well #989 (7S14E29CDC1). There is no calibration well in the Rangen cell, but well #989 is in the model cell immediately northeast from the Rangen cell and is the closest well used in calibration. The simulated water level in this well is systematically more than 20 feet lower than observed level. Also shown on Figure 4.7 is a comparison between simulated and observed water levels in well 7S14E33BBB1. This well was identified as calibration well #992, but for unknown reasons was not included in the target calibration data set. Figure 4.7 shows that ESPAM2.1 also underpredicts the water level in this well.

In 2008 the IDWR completed a monitoring well (7S14E32SENW, aka the "Rangen Monitor Well") on the plain just above the Curren Tunnel (Farmer, 2009). Observations from this well could not be used in ESPAM2.1 calibration because measurements did not begin until the very end of the model calibration period. Nevertheless, the range of observed values reasonably can be compared to simulated water levels in the Rangen cell for the last few years of the calibration period. This comparison is shown in Figure 4.8. It can be seen that ESPAM2.1 predicts recent water levels in the Rangen cell that are substantially lower than what has been observed in the Rangen Monitor Well.

The underprediction of water levels near Rangen is partly a result of the fact that discharge targets were weighted more heavily than water level targets in the calibration process. If predicted water levels were too low, PEST could still meet the more important discharge target by increasing the drain conductance. This is problematic because it embodies, in the drain conductance parameter, a mischaracterization of the real physical relationship between water levels and flows at Rangen. This, in turn, results in mischaracterization of change in drain flow as a result of simulated change in water level due to curtailment. If the calibrated drain conductance parameter is too high, the benefits to Rangen from curtailment will be over-stated.

That the Rangen discharge calibration is as good as it is despite the underprediction of surrounding water levels illustrates another important modeling concept…that good calibration is not necessarily evidence of correct physical representation (Bredehoeft, 2005).

Table 4.1 lists the ESPAM2.1 drain parameters determined by PEST for target springs in the Billingsley Creek area. Drain elevation assumptions were generally chosen to reflect actual elevations, or a range of actual elevations where multiple drains were used. PEST was allowed to adjust drain conductances as needed to match spring discharge targets using simulated water levels. As can be seen in Table 4.1, the calibrated conductances range over 4 orders of magnitude. This extremely large variation suggests that the set of calibrated parameters is quite fragile and that PEST can readily find alternative parameter sets that provide acceptable calibrations.

4.5.2 Comparison to Observed Conditions in Rangen Area

The ESPAM2.1 posits a strictly linear relationship between water level in the Rangen cell and discharge from the Rangen drain. The ESPAM2.1 drain conductance has a calibrated value of 4.85 cfs/foot, meaning that a one foot increase in water level in the Rangen cell will result in a 4.85 cfs increase in drain discharge. The only water level observations close enough to Rangen to be considered within the Rangen cell are those from the Rangen Monitor Well. Hinckley (2012) demonstrates that Curren Tunnel discharge is not the simple linear function of nearby water level represented in ESPAM2.1, a fact that appears also to be acknowledged by Rangen experts (Brannon, 2009). If this relationship is in fact non-linear, the principle of superposition cannot be used to reliably determine the effects of curtailment on Rangen flows.

Even if a linear relationship were to be derived from Hinckley fig 19, it suggests that a one foot increase in nearby water level would cause a discharge increase of 1.37 cfs rather than the 4.85 cfs embodied in ESPAM2.1. In this case the ESPAM2.1 overstates the benefit from curtailment by nearly a factor of 4.

Observed water level in the Rangen monitor well varies over a range from about elevation 3151 ft to 3166 ft (msl). Farmer (2009) estimated the elevation of the outlet of the Curren Tunnel to be 3145 ft (msl) and the elevation of the lower springs to be about 3100 ft (msl). This suggests that the saturated thickness of the aquifer above the Tunnel outlet is not greater than 6-21 feet and that the saturated thickness of the aquifer above the lower springs is in the range of 50-65 feet. Water levels in the monitor well vary seasonally by about 5 feet, and predicted (by ESPAM2.1) water level change in the Rangen cell from curtailment is about 4 feet. These changes are nearly 100% of the saturated thickness above the Tunnel and about 10% of the thickness above the lower springs, further indicating that the requirements for superposition are not met at Rangen.

Hinckley (2012) has shown that for a given water level in the Rangen Monitor well, the discharge from the Curren Tunnel can vary by 4 cfs. In other words, with *no difference* in observed water level, observed discharge varies by 100% of its average value over the observation period. Similarly, Hinckley has shown that a given level of Rangen discharge can be associated with water levels that vary over a 2.5-foot range. This casts further doubt on the accuracy with which ESPAM2.1 can predict the benefit to Rangen from curtailment.

Figure 4.9 shows the ESPAM2.1 change in calibrated values of aquifer transmissivity in the vicinity of Rangen. Notable on this figure is the fact that transmissivities increase in magnitude closer to the canyon rim above Rangen. This is the opposite of what would be expected as the aquifer thins out and saturated thickness decreases. Some of this is undoubtedly a result of the higher weighting placed on discharge targets than on water level targets, but Johnson (2011) suggests it may be a result of calibration using the assumption of constant transmissivity. It is likely that fracture or conduit flow, more than porous media flow, dominates hydraulic behavior near springs in the rim area. These other flow paradigms are not reflected in any of the MODFLOW constructs used in ESPAM2.1.

Farmer (2009) describes a geological discontinuity in the vicinity of Rangen where the Quaternary basalt forming the main aquifer effectively ends at the canyon rim. The Quaternary basalt below the rim immediately west of Rangen is postulated to have flowed down a "ramp" from the southeast. Because of this discontinuity, groundwater entering this lower basalt flow has to come from the southeast rather than directly through the Rangen area. However, in ESPAM2.1 there is a simulated groundwater flow of 320 cfs across this discontinuity from the Rangen cell into the cell containing Tucker and Stewart Springs. As a result of this high flux, simulated water level in the Tucker/Stewart cell is very high (above actual ground surface) and causes a simulated groundwater gradient sloping to the south. Hinckley (2012) points out that the observed groundwater gradient in this area is in the opposite direction from that simulated by ESPAM2.1. These discrepancies reveal serious model misrepresentation of detailed aquifer behaviour in the Rangen area, and raise doubt as to the accuracy of model predictions there.

4.5.3 Comparison of ESPAM2.1 with Previous Versions of ESPAM

ESPAM1.1 and ESPAM2.0

The IDWR carried out a comparison of ESPAM1.1 and ESPAM2.0 performance (Sukow, 2012a) using the paradigm of the generic curtailment scenarios originally run by IWRRI for ESPAM1.1 (Contor, et al, 2004). This comparison utilized a steady-state version of the primary input file (the .wel file) in both the ESPAM1.1 and ESPAM2.0 and simulated the curtailment to 5 generic dates. Table 4.2 reproduces the results of this comparison for the generic curtailment date of January 1, 1961.

Table 4.2 makes two different comparisons. The first compares results from using the ESPAM1.1 input file in both the ESPAM1.1 and ESPAM2.0; this comparison illuminates the change in model results that can be attributed mainly to changes in model structure and parameters (which have been described above). The second compares results between the two models each using their own input file; this comparison illuminates the change in model results that can be attributed mainly to changes in input data. With respect to spring flows below Milner, the IDWR analysis found that flows due to 1961 curtailment increased from 352 cfs to 454 cfs using the ESPAM2. The analysis also concluded that roughly 75% of this change was the result of changes in model input data, primarily the use of more recent years for estimation of irrigated acreage and irrigation water requirements. This highlights the sensitivity of ESPAM2 results to conditions in particular years. Review of updated comparisons using ESPAM2.1 (Sukow, 2012b) leads to the same conclusion.

ESPAM2.0 and ESPAM2.1

Shortly after its release, an error was discovered in the input data for ESPAM2.0. The error arose in the calculation of the water budget in the Mud Lake area and caused an overestimate of aquifer recharge of approximately 89,000 acre-feet/year in that area of the model domain. The error was corrected and the model was recalibrated creating ESPAM2.1, which was made available on November 16th of this year.

The water budget error at Mud Lake was on the order of 1% of the overall ESPAM water budget. It was expected that the relatively small size of this error and its location at the far northeastern part of the model domain would not result in significant changes to the model at its western end.

Table 4.3 shows the change in calibrated values of drain conductance parameters in the Thousand Springs reach and Rangen area, between ESPAM2.0 and ESPAM2.1. As can be seen in Table 4.3, many of the conductances in the western end of the model domain changed by amounts substantially greater than the 1% change in water budget associated with the correction. The conductance for the Rangen drain decreased by about 4%, but some drain conductances in the area changed by nearly 1000%. Figure 4.9 shows how transmissivity values changed as a result of the error correction. Some cell transmissivities in the area near Rangen changed by as much as 500%. As will be discussed in a later section, these changes in conductance and transmissivity are carried directly into the superposition models used to calculate the flow changes resulting from curtailment. Large changes in calibrated parameter values suggest that ESPAM2.0 and ESPAM2.1 may be over-parameterized, and that other comparable calibration solutions easily can be reached with only minor perturbations in model assumptions. This substantially raises the level of uncertainty in model predictions, since other models can readily be found (by PEST) that are as well-calibrated but have very different parameter values in specific locations.

Further evidence of unexpectedly large changes in ESPAM2.1 is seen in Figure 4.10, which depicts the boundary of the 5% and 10% trimlines for Rangen using ESPAM2.0 and ESPAM2.1. Figure 4.10 shows that the area encompassed by the 5% trimline is substantially larger with ESPAM2.1, but that this expansion is mainly in areas on the opposite side of the Malad Gorge from Rangen. Given the fact that the Gorge severs the Quaternary basalts that form the aquifer (Hinckley, 2012), it is difficult to see why wells west of Bliss should now be viewed as having increased effect on Rangen flows simply because of a small data error at Mud Lake.

4.6 Model Uncertainty

The ESPAM2 is, like all models, a simplified representation of reality, and this leads to model uncertainty. When viewed from a distance, the generalizations and simplifications made to construct the model may be sufficient to support regional scale analyses. However, when called upon to represent highly localized conditions such as those governing discharge from specific outlets of a specific spring complex, the generalizations and simplifications can introduce significant error into model results. Actual subsurface conditions within the ESPA are understood only in specific locations where lithology has been observed (e.g., boreholes and outcrops) and where hydraulic characteristics have been measured (e.g., pump tests). Observations of ESPA geology suggest it is highly complex, comprised of overlapping fractured basalts interspersed with sedimentary formations, with hydraulic characteristics that can vary substantially over short distances (Lindholm, 1996; Hinckley, 2012).

4.6.1 Overview - General Dimensions of Model Uncertainty

Model uncertainty has several dimensions, and these have been described in various submittals to the ESHMC (e.g., Brendecke, 2009a,b; 2012). In a nutshell, the principal dimensions of model uncertainty are those associated with model conceptualization, with model input and with model calibration. While all of these dimensions are important, conceptual uncertainty is fundamental. No amount of data improvement, re-sampling or recalibration can correct errors stemming from incorrect (or simply incomplete) model conceptualization (Bredehoeft, 2005).

Model conceptualization involves the identification and adoption of a model framework that the modeller believes can properly represent the behavior of the underlying real system. At a practical level it is the selection of a modeling code (in the present case MODFLOW) and the formulation of the model structure (e.g., defining the domain, deciding whether to operate it as a confined or unconfined system, adopting cell sizes, layering, boundary conditions, etc.). Previously in this chapter we have examined how many of these conceptual aspects of ESPAM2.1 fail to reflect observed characteristics of the aquifer system in the Rangen area. These failures lead to conceptual uncertainty in the ESPAM2.1.

Rigorous evaluation of conceptual uncertainty is difficult. There may be a large number of plausible conceptual models of an aquifer system and these models can't be rigorously evaluated until they are built. As a result, this critical dimension of model uncertainty is often "swept under the rug" in favor of more constrained and tractable evaluations that focus on input data and calibration. In the case of ESPAM2.1, this conceptual uncertainty bears directly on its suitability in the present matter.

Once a conceptual model has been identified and formulated, it must be populated with input data reflective of the important aspects of the aquifer water budget. In the case of ESPAM2.1, these data include precipitation, tributary underflows, irrigated acreage, crop distributions, surface water supplies, water application methods and efficiencies, etc. Each of these input data types carries its own uncertainties that can stem from, among other things, the inability to measure a condition accurately (or at all) and from the spatial or temporal resolution of measurements. Sometimes these uncertainties can be reduced by further data collection efforts, though these may be time-consuming and expensive. The effects of input data uncertainty can sometimes be explored through sensitivity analysis or through Monte Carlo analysis, which seeks to translate probabilistic descriptions of model input data to probabilistic descriptions of model output.

Once the conceptual model has been populated with input data, it must be calibrated. The calibration process has been addressed previously in this section. Calibration uncertainty essentially reflects the fact that many combinations of model parameter values (which in the case of ESPAM2.1 include aspects of the aquifer water budget) may lead to equally well-calibrated models. The uncertainty arises because the predictions made by these equally well-calibrated models may be significantly different.

4.6.2 IDWR Uncertainty Analysis

The uncertainty of ESPAM2.0, and selected aspects of ESPAM2.1, have been explored by the IDWR using a technique called "Predictive Analysis" that is available as part of the PEST software (Watermark, 2005). Predictive Analysis is described in the PEST documentation as

> "… the task of calculating the effect of parameter uncertainty, as estimated through the calibration process, on predictive uncertainty."

Predictive analysis essentially answers the question "If I use slightly different values for selected model parameters, do I get different values for key model results?" The analysis requires assumptions about the meaning of "slightly different" and whether such differences are small enough that the model can still be considered calibrated. The analysis does not explore alternative conceptual representations of aquifer hydrogeology, although it can be used in a limited way to explore input data uncertainty.

Table 4.3 summarizes the predictive analysis carried out by the Department (Wylie, 2012c,d) for ESPAM2.0, showing updates for selected portions using ESPAM2.1. The analysis made several simplifying assumptions to make the work computationally more efficient; for example, it assumed that pumping stress for entire Water Districts could be applied at the centroid of each District without loss of accuracy. The predictive analysis was designed to be generic, and did not examine parameter sensitivity of predictions of Rangen discharge. The conclusion that can be drawn from Table 4.3 is that parameter uncertainty variable of the model domain (e.g., the relationship between pumping in Water District 34 and reach gains between Blackfoot and Minidoka is apparently larger than that between pumping in Water District 130). The important thing to remember with this analysis is that it relies on a single conceptual model and does not explore the uncertainty that arises from improper conceptualization of local geologic and hydraulic conditions that influence discharge of specific spring complexes, such as those at Rangen.

4.6.3 Rationale for alternative models

In the uncertainty evaluation carried out for the ESPAM2.1, the model and parameter structure are assumed fixed, as are many data inputs. This approach is valuable in illuminating those parameters for which further investigation might reduce the uncertainty of the chosen model (James, et. al., 2009), but does not address larger questions of model uncertainty described above. More exhaustive evaluation approaches, such as Monte Carlo simulation, may shed greater light on the probability distributions of model errors. However, unless such approaches address all the dimensions of model uncertainty, including conceptual uncertainty, they too will be incomplete.

Conceptual uncertainty can only be addressed by considering alternative models. The poor correspondence between ESPAM2.1 assumptions about hydrogeology and aquifer behavior in the Rangen area indicate that at the very least a refined version of ESPAM2.1 is required. One very preliminary set of refinements are discussed in a later section of this report.

4.7 Limitations of ESPAM2

While it is clearly an improvement over its predecessor, several important features are the same in ESPAM1.1 and ESPAM2.1. The two are still conceptually the same regional model. Differences between them are largely the result of differences in input data and in values of calibration parameters resulting from the use of that input data. Both models represent the details of the Rangen spring complex and the surrounding geology in highly simplified form, omitting several key features and that would make significant differences in predicted benefits of curtailment.

Particularly important to the present case is the fact that ESPAM2.1 systematically underestimates water levels in the Rangen area. Because simulated heads are too low in the cells above Rangen, the calibrated drain conductances have to be made higher in order to meet the discharge calibration targets. This means that the drains are overly-sensitive to small changes in head. This over-sensitivity is carried into the superposition model used for curtailment, with the result that changes in spring flows are substantially over-predicted.

For these reasons, the ESPAM2.1 is subject to the same general limitations as ESPAM1.1, despite the increased attention given to the use of springs as calibration targets. That ESPAM2.1 can fairly closely mimic the observed past behavior of a spring complex is not proof that it sufficiently represent hydrogeologic reality to accurately predict future behaviour of that complex, especially under aquifer water use conditions (e.g., curtailment of large amounts of junior groundwater pumping) that are radically different from those extant in the model calibration period.

The ESPAM2.1 documentation describes limitations on model usage, highlighting the facts that a number of simplifying assumptions had to be made and that many components of the model water budget were uncertain. The documentation cautioned that ESPAM2.1 is a regional ground-water model best used for broad-scale predictions.

5.0 SIMULATION OF CURTAILMENT OF JUNIOR GROUNDWATER RIGHTS

5.1 Background

IDWR practice has been to create superposition versions of the ESPA groundwater model for use in evaluating curtailment (and other) scenarios. Superposition models are used primarily for reasons of convenience; it is faster and easier to perform analyses with superposition models than it is with "fully populated" models. A fully populated model contains all the water budget (input) data and parameters used in model calibration; outputs from a fully populated model can reflect simulated values of characteristics that may be directly observable in the aquifer. However, to examine effects of changes in input data, such as reduced pumping withdrawals, it is necessary to make two runs of a fully populated model and then determine effects by differencing the results of the two runs. The use of a superposition model allows this differencing to be accomplished in a single model run.

A superposition model preserves the parameters of the flow relationships between model cells but sets the initial condition of the groundwater flow regime to one of zero flux. Existing fluxes are eliminated by setting all aquifer heads and elevation differences to zero. The aquifer is converted, conceptually, into a still pool but one in which all the water molecules preserve fixed, predetermined relationships to one another. The relationships that are preserved in a superposition model are embodied in the calibrated parameters governing flow rates and responses: transmissivity, specific yield, conductance (of drains, riverbeds, and general head boundaries) and seepage rates from canals. The effect of a selected model stress, such as a reduction in groundwater withdrawal, can then be evaluated with the superposition model simply by applying that incremental stress and examining how heads and fluxes (including reach gains and drain flows) have changed from their zero condition.

The principle of superposition relies on the assumption that the system being modeled behaves in a completely linear way…that is, that flow relationships are independent of flow magnitude. In a linear model, the rate of flow caused by a half-foot difference in water level between two cells will be the same whether the cells contain water 1 ft or 1000 ft deep. Superposition models perform identically at all levels of assumed stress change, even those outside their range of calibration. If the system being simulated exhibits important non-linear behaviors, such as those that have been described in preceding sections of this report, a superposition model can introduce significant error into the analysis of effects of stress changes.

The practice of the IDWR has been to define three superposition versions of the ESPAM, a steady state version (dubbed "SuperSS"), and two transient versions (dubbed "SuperTransient10yr_monthly" and "SuperTransient150yr"). The transient versions allow simulation of how assumed stress changes evolve over time, the former reflecting a repeated seasonal pattern of conditions and the latter reflecting a constant annual pattern. The constant annual pattern is used to assess the speed at which the aquifer reaches equilibrium (steady state) conditions after introduction of a change.

Simulation of curtailment of groundwater irrigation rights junior to Rangen's 1962 Curren Tunnel water right has been carried out with ESPAM2.0 by both the IDWR and by Rangen experts. Simulation of curtailment using ESPAM2.1 has been carried out in a generic sense by the IDWR (Sukow, 2012b) and for the Rangen water rights by AMEC. These simulations are briefly described and evaluated below.

5.2 IDWR Curtailment Analyses

5.2.1 Generic Curtailment Analysis

As part of the development of ESPAM2.1, the IDWR carried out a comparative analysis of the effects of curtailment as simulated by ESPAM1.1, ESPAM2.0 and ESPAM2.1. The simulated curtailments were those described by Contor, et.al. (2005) for ESPAM1.1. The curtailments did not reflect priority dates of any specific water rights nor were they limited spatially to the the Area of Common Groundwater defined in Rule 50 of the Conjunctive Management Rules. The curtailment dates used in the analyses were January 1 of the years 1870, 1949, 1961, 1973 and 1986. The January 1, 1870, curtailment date reflected curtailment of all groundwater use in the model domain except that occurring under tribal water right settlement agreements.

The January 1, 1961, curtailment is roughly comparable to that which would occur under the present delivery call for Rangen's July 13, 1962, water right. Table 4.2 in the preceding section showed the results of the hypothetical 1961 curtailment using ESPAM1.1 and ESPAM2.1.

5.2.2 Rangen Curtailment Analyses

In its document production of June 12, 2012, the IDWR produced model files containing results of curtailment analyses for the present Rangen delivery call. These files indicate that the Department evaluated the effects of July 13, 1962, curtailment with ESPAM2.0 using various "trimline" assumptions.

The "trimline" defines a zone of exclusion outside of which the benefits of curtailing a well are less than a threshold percentage of the amount of water use curtailed, as determined by the groundwater model. The trimline concept was originally adopted by former Director Karl Dreher in his 2005 Orders stemming from the delivery calls of Blue Lakes Trout, Clear Springs Foods, the Surface Water Coalition, Rangen, Inc., and others. Director Dreher adopted a 10% trimline and stated in hearing testimony that he viewed this as a minimum level of model uncertainty, noting that model uncertainty had not been quantified. He went on to say that:

> *"…I made the determination it was not appropriate to curtail such junior priority ground water use if, in fact, we didn't know whether curtailment would result in a meaningful amount of water reaching the calling senior right."* (Transcript at 1167: 4-80)

Table 5.1 summarizes the results of the IDWR curtailment analyses using ESPAM2.0. The analyses considered trimline thresholds between 0.2% and 10%, as well as trimlines limited only by the Rule 50 Area of Common Groundwater Supply and by the ESPAM2.0 model domain. As

the trimline threshold decreases the area encompassed by curtailment increases. As shown in Table 5.1, there are a total of 406 groundwater irrigated acres relying on rights junior to Rangen's 1962 priority within the 10% trimline; there are a total of 565,023 groundwater irrigated acres within the model domain relying on rights junior to Rangen's1962 priority.

Table 5.1 shows that curtailment of the junior groundwater rights within the 10% trimline would immediately eliminate 1,445 acre-feet of groundwater pumping and, at steady state, would cause total modeled flow at the Rangen springs to increase by 0.19 cfs (141 af/y assuming year around flow). This increase in modeled spring discharge represents 9.5% of the pumping foregone by the curtailed wells and, assuming a permitted groundwater diversion rate of 1 miners inch (1") per acre, 0.66% of the curtailed water rights. It would take somewhat less than a year for discharge to reach 90% of this modeled steady state increase.

Curtailment of the junior groundwater rights within the entire model domain would immediately eliminate 1.46 million acre-feet (MAF) of groundwater pumping and, at steady state, would cause modeled discharge from the Rangen spring complex to increase by 18.07 cfs. This increase represents 0.9% of the pumping foregone by the curtailed wells, and 0.06% of the curtailed water rights. It would take approximately 16 years for modeled discharge to reach 90% of this steady state increase.

Foregone groundwater use that is not simulated to accrue to Rangen would accrue to other connected river reaches, springs and baseflows, including those on which there are no water rights or diversions, those on which there are no delivery calls, those on which approved mitigation plans are already in place, and those on which diversions occur under water rights junior to those of the curtailed rights.

5.3 Rangen Analysis

In its December 13, 2011, delivery call Rangen included a curtailment analysis (Exhibit 11 to the petition) carried out by its experts (McGrane et.al., 2011). The details of this analysis were requested at the outset of discovery for this case, but were not produced by Rangen until November 28th of this year. Accordingly, the conclusions below are based primarily on a facial interpretation of Exhibit 11 and may be supplemented when time permits a more careful examination of Rangen's late production.

The Rangen analysis appears to be a transient analysis using average monthly stresses. The use of a transient, average monthly analysis permits the display of simulated seasonal effects of curtailment. It does not appear that the version of ESPAM2.0 used for the analysis is the final calibrated version. The analysis recommends against the use of the trimline concept and concludes with a recommendation that Rangen seek curtailment of all junior (to July 13, 1962) groundwater irrigation rights within the ESPAM2.0 domain. As noted above, this would immediately dry up 565,023 acres of groundwater irrigated land.

Figure 5.1 is reproduced from Exhibit 11 of the Rangen petition. It shows that curtailment would achieve a simulated annual average increase in total Rangen discharge of 17 cfs after 20-plus

years of curtailment. After twenty five (25) years of continuous curtailment, simulated minimum seasonal flows from the Rangen complex would increase by about 9 cfs.

Presumably the curtailed groundwater acreage and water use amounts implicit in the Rangen analysis are similar to those of the IDWR analysis with no trimline, and that similar conclusions could be drawn regarding the portion of curtailed use and water rights that would accrue to Rangen's benefit.

5.4 Rangen Curtailment Using ESPAM2.1

AMEC has carried out analyses of curtailment for Rangen's 1962 water right using ESPAM2.1. These analyses were carried out using the assumption of a 10% trimline. A 10% trimline assumption was adopted based on precedent; previous curtailment analyses and orders by the IDWR have used this assumption, which stems from Director Dreher's Orders in 2005.

AMEC compared the spatial extent of the 5% and 10% trimlines for ESPAM2.1 as defined based on steady-state response functions published by the IDWR (http://www.idwr.idaho.gov/Browse/WaterInfo/ESPAM/model_files/Version_2.1_Current). Figure 4.10 shows the 10% and 5% trimlines for ESPAM2.0 and ESPAM2.1. The 10% trimline is the same for both models, but the 5% trimline for ESPAM2.1 encompasses a larger area than that for ESPAM2.0. This is presumably the result of recalibration due to correction of the Mud Lake data error described previously, though it is difficult to see why a small change in input data in the opposite end of the model domain would cause such a large change in the trimline. It is noteworthy that the extension of the trimline occurs in the area west of Bliss, which is separated from the Rangen area by the Malad Gorge.

Table 5.2 summarizes the steady state results of the 10% trimline curtailment using ESPAM2.1. Curtailment to the 10% trimline has results nearly identical to the ESPAM2.0 analysis done by the IDWR. This curtailment would immediately dry up 406 acres of groundwater irrigated land and eliminate 1,446 acre-feet of groundwater use. Total simulated flow at Rangen would increase 0.21 cfs, which is slightly higher than the 0.19 cfs predicted by the IDWR analysis. This small difference may be attributable to changes in the transmissivity distribution that occurred in recalibration of ESPAM2.1.

6.0 Alternative Conceptual Models

This section describes the development of two alternative conceptual models (labelled #1 and #2 below) of the ESPA in the immediate area of the Rangen complex. The aim of this effort is not to present a definitive reformulation of ESPAM2.1, but to illustrate how a few relatively minor changes to its conceptual structure, suggested by detailed hydro-geologic review, could result in significantly different conclusions from a curtailment analysis. In order for either of these alternative conceptual models to be fully developed, it would be necessary to perform similar analyses at other spring complexes as were presented in the foregoing sections of this report and to extend the reach of calibration from that used herein. Nevertheless, the results of these

preliminary steps at more realistic representation of local hydrogeology illustrate the potential for significant conceptual uncertainty in the application of ESPAM2.1 to localized problems.

6.1 Description of Modifications to ESPAM2.1

The alternative modeling effort focused on making small changes to the construction of ESPAM2.1 to explore what effect these changes have on simulated Rangen discharge and simulated water levels in the vicinity of Rangen. Concepts for these changes are based primarily in hydrogeologic analyses and interpretations presented in Ralston (2008), Farmer (2009) and Hinckley (2012) and on discussions with Neal Farmer on August 22, 2012.

6.1.1 Horizontal Flow Barrier

The main geologic formations that influence the groundwater flow and spring discharge near the Hagerman area are the Quaternary basalts that form the ESPA and the less permeable Tertiary formations (e.g., Glenns Ferry) that underlie it. Current geologic understanding of the Hagerman area is that the ESPA effectively terminates along the Hagerman rim and that the underlying formations restrict subsurface flow from it into the Hagerman Valley. At the south end of the rim, however, Quaternary basalt flows form a "ramp" (Farmer, 2009) creating a pathway to feed lower-elevation springs such as Tucker and Stewart as shown in Figure 6.1. Between this ramp and the rim is a geologic discontinuity, possibly faulting, that restricts groundwater movement directly from the rim to the lower elevation springs. Observed gradients indicate that groundwater flows into this lower area from the southeast rather than the northeast.

To reflect this geological feature, a horizontal flow barrier (Hsieh, 1993) was inserted between columns 12 and 13 for the cells in rows 42 and 43 of the model domain. For model #2, this barrier was shortened to only row 42, as shown in Figure 6.2. A horizontal flow barrier restricts groundwater flow between the cells for which the HFB is defined. With this barrier in place, the preponderance of flow moving southwest through the ESPA must go around the discontinuity to reach the lower springs.

6.1.2 Multiple Drains

Groundwater flows from the Rangen complex emerge at several locations. Farmer (2009) and personal observation note at least two discharge areas, the Curren Tunnel and a set of springs emerging from the slope below it. Farmer estimated the Tunnel to be at elevation 3145 ft (msl) and the lower springs to be at elevation 3100 ft. Koreny (2011) presented spring survey data indicating a Tunnel elevation of 3150 ft "plus or minus two feet." Covington and Weaver (1991) note an elevation of 3138 ft for the "Rangen spring." Elsewhere in the Thousand Springs reach, complexes with discharge points having a range of elevations have been represented using two drains. Given the range and uncertainty in elevations of discharges at Rangen, it seems appropriate to use the same multiple drain construct to represent Rangen as was used in other nearby locations.

Accordingly, another modification made to the alternative models was to represent the Rangen complex using two drains. A new upper drain (DRN218) was added to the Rangen cell, and to the CRIV group. In both models the lower drain was given an elevation of 3100 ft. In alternative model #1 the upper drain was given an elevation of 3152 ft, while in model #2 it was given an elevation of 3148 ft, thus bracketing the upper elevation estimates for the Tunnel presented by Koreny (2011).

6.1.3 Removal of GHB Cells

As noted in Section 4, the use of General Head Boundaries (GHBs) to reflect unmeasured flows from the ESPA to the Snake River effectively undid the removal of the Hagerman Valley from the model domain. Present geologic understanding is that the Hagerman Valley is not part of the ESPA, yet the use of GHBs along the Hagerman rim implies that the ESPA continues through the valley to the river.

It is conceivable that ESPA discharges could be made to the river at the northern and southern edges of the Hagerman Valley. Covington and Weaver note the presence of springs at river level downstream of Lower Salmon Falls dam. Low elevation springs and seeps also exist in the area of the Hagerman Fish Hatchery operated by the State of Idaho.

The third modification made in the alternative models was to remove four GHB cells immediately north of Rangen to prevent simulation of ESPA flows through the Hagerman Valley. This reconfiguration is shown on Figure 6.3. This removal forces baseflows in the Buhl to Lower Salmon Falls reach to move through the remaining GHB cells defined in ESPAM2.1.

6.1.4 Increased Weighting on Recent Rangen Flows

A notable feature of the ESPAM2.1 calibration and validation is the over-prediction of Rangen flows in recent years. Given that any management action would look forward from the present, it seems appropriate that greater emphasis should be placed on simulation of current aquifer behavior. Accordingly, a further modification undertaken in Alternate Model #2 was to assign increased calibration weight to Rangen flow observations after the year 2000. The aim of this modification was to improve the model simulation of Rangen discharge in recent years.

6.2 Calibration of Alternative Models

6.2.1 General Approach

The alternative models were calibrated using the PEST software. Calibration adjustments were limited to parameters in the CRIV group; no recalibration of model transmissivity or specific yield was done, nor were any water budget terms adjusted in the calibration.

Calibration targets for the alternative models were the same as those used in ESPAM2.1, except for the addition of water level targets for PEST well #992. This well, which lies immediately northeast of the Rangen cell, was listed as a target for ESPAM2.1 but was apparently never

used. This inclusion of well #992 added 166 additional target values to the calibration data set. These were given calibration weights the same as those used in ESPAM2.1 for other transient water level targets.

6.2.2 Calibration Results Model #1

Figure 6.4a shows the results of calibration of model #1 for the Rangen discharge and Figure 6.5a shows the results for water levels in wells 989 and 992.

In ESPAM2.1, modeled groundwater levels in calibration well 989 are 20 ft lower than observed levels, and in well 992 the modeled levels are around 2 to 8 ft lower than observed levels (well 992 was apparently not used in the ESPAM2.1 calibration).

In alternative model #1, simulated water levels are higher in both wells, matching observations better than in ESPAM2.1. The most marked improvement is in well 989, which was underpredicted by approximately 20 feet in ESPAM2.1; with model #1 the underprediction is about 10 feet. ESPAM2.1 underpredicted water levels in well 992 by about 5 feet, though somewhat less in more recent years; with model #1 there is good match to water levels in well 992, though there is a slight overprediction in recent years.

The simulated Rangen discharge in model #1 is nearly identical to ESPAM2.1. From the foregoing I would conclude that the calibration of model #1 in the Rangen area is at least as good as that of ESPAM2.1.

6.2.3 Calibration Results Model #2

Figure 6.4b shows the results of calibration of model #1 for the Rangen discharge and Figure 6.5b shows the results for water levels in wells 989 and 992.

In alternative model #2, simulated water levels are not as high as with model #1, but correspondence with well 989 is still improved over ESPAM 2.1. Calibration to flow at Rangen is somewhat poorer in the early years of the calibration than is ESPAM2.1, but calibration in recent years is much better. Model #2 appears to resolve the overprediction problem noted for ESPAM 2 ? in recent years.

6.3 Curtailment Analysis with Alternative Models

Both alternative models were run to simulate curtailment of junior groundwater uses within a 10% trimline. This trimline is consistent with past practice and with IDWR water rights transfer policy. The results of these runs are shown in Table 6.1. Also shown in this table are the results of the same curtailment analysis using ESPAM2.1.

It can be seen by this comparison that the relatively minor modifications made to ESPAM2.1 to better reflect local hydrogeology have substantial effect on simulated benefits to Rangen from curtailment. In the case of alternative model #1, the benefit from curtailment is roughly half that

predicted by ESPAM2.1. In the case of alternative model #2, the benefit is about 5% of that predicted by ESPAM2.1.

6.4 Conclusion

The foregoing alternative model simulations demonstrate how sensitive the predictions from ESPAM2.1 can be to the model representation of local hydro-geologic conditions. Relatively minor changes in ESPAM2.1 conceptualization, made to more closely reflect the local conditions at Rangen, result in model predictions that differ substantially from those of ESPAM2.1. The substantial differences in model predictions highlight the potential magnitude of conceptual uncertainty in ESPAM2.1, a dimension of uncertainty not addressed in the IDWR's predictive analysis.

* SRBA Partial Decree.

** According to a memorandum from Cindy Yenter to Karl Dreher dated December 15, 2003, Rangen's submitted historical flow numbers show that flows have not been available to support water right number 36-7694 since October 1972, which predates the priority year of the right by nearly 5 years. Additionally, during the water right development period flows did not exceed 50 cfs, which is the total of water rights 36-15501 and 36-2551.

INTRODUCTION

The Enhanced Snake Plain Aquifer Model (ESPAM) is an important tool used by the Idaho Department of Water Resources (IDWR) in estimating impacts between ground water use and surface water resources to support water management decisions (Cosgrove and others, 2006). A significant portion of the water that discharges from the aquifer is from springs that are located along the Snake River. The Near Blackfoot to Neeley reach of the Snake River (defined by two stream gauging stations) includes large springs that discharge into the Snake River and the Portneuf River (Figure 1).

The objectives of this report are as follows: 1) describe the hydrogeology in the general vicinity of the Near Blackfoot to Neeley reach of the Snake River, 2) describe how the model represents the hydrogeology of this area and 3) provide recommendations relative to model changes to better represent the field conditions. The report is based on a review of available reports (citations provided in the text), discussions with individuals who work for the IDWR, the University of Idaho (UI) and have worked with the U.S. Geological Survey (USGS) and field site visits in March and October of 2007.

OVERVIEW OF THE AREA

The Near Blackfoot to Neeley reach of the Snake River includes the American Falls Reservoir and is located adjacent to the south margin of the of the Snake River Plain of eastern Idaho. Mundorff (1967, page 7) describes the geologic setting of the area as follows.

> "The Snake River Plain is underlain by a thick sequence of basaltic lava flows, interbedded pyroclastics and sedimentary deposits. The sequence accumulated in a structural trough between much older rocks of the mountain ranges that flank the trough along the northwest and southeast. The total thickness of the fill in the trough is not known, but it is believed, on the basis of geophysical evidence, to exceed 10,000 feet in some places.…
>
> The central part of the plain is generally higher than the margins and contains many lava domes and cones, indicating that at least in the late stages of volcanism, the basalt spread from the central part of the plain towards the northwest and southeast flanks. In the process, the Snake River was crowded against the southeast flank of the plain. Sedimentary interbeds, deposited in stream channels, flood plains and lakes, are thick and extensive along and adjacent to the present course of the Snake River, whereas they are thin or absent toward the central part of the plain."

Mundorff (1967, pages 7-8) provides the following description of the ground-water system.

> "The uppermost few thousand feet of basalt flows, pyroclastics and sedimentary interbeds compose the Snake River Group. These rocks form a great aquifer system – the Snake Plain aquifer – that stores and transmits large amounts of water … Chief sources of recharge to the aquifer are percolation from the channels of the Snake River, Henrys Fork and other streams; percolation from canals and irrigated tracts; and underflow from peripheral valleys and highlands…. The margin of the Snake Plain aquifer is the contact between the

basalt and the consolidated rocks or the sedimentary deposits of lower permeability….The aquifer discharges to the Snake River chiefly in two reaches: between the mouth of the Blackfoot River and American Falls (American Falls Reservoir reach), and between Milner Dam and Bliss (Hagerman Valley reach). Discharge in these two reaches is caused by the specific spatial relationships of the aquifer to aquitards (geologic units of low permeability) in the reach. In the Hagerman Valley reach, the contact between the aquifer and the underlying aquitard intersects the canyon of the Snake River at an altitude generally 100-200 feet above river level, and springs issue at or above that contact. In the American Falls Reservoir reach the contact is generally 20-45 feet above maximum reservoir level."

GEOLOGIC SETTING

Regional Geologic Setting

The Near Blackfoot to Neeley reach of the Snake River including the American Falls Reservoir is underlain mostly by sediments with a large mass of basalt located to the north and northwest. Figure 2 is a geologic map of the area taken from Whitehead (1992) that shows the sediments as alluvium (Qa), wind blown deposits (Qw) and older alluvium (Qts). The basalt shown northwest of the river is identified as younger basalt (Qb) or basalt (Qtb). The general relationship between basalt and sediment is shown on two figures taken from Whitehead (1992). Figure 3 shows the thickness of Quaternary basalt whereas Figure 4 shows the thickness of sedimentary rocks. The two figures show the transition from a basalt-dominated subsurface in the center of the Snake Plain to a sedimentary-dominated subsurface in the vicinity of American Falls Reservoir. In addition, Figure 3 shows that the thickness of Quaternary basalt is greater northeast of the American Falls Reservoir than in the immediate vicinity of the reservoir.

Local Geologic Setting

The local geologic setting includes Tertiary and Quaternary basalt, mostly fine-grained sediments associated with deposition in a lacustrine environment (Raft Formation and American Falls lake beds) and gravel deposits associated with the Snake and Portneuf Rivers. Information on the local geologic setting is provided from four primary papers. Trimble and Carr (1961) describe the geology of the southern portion of the American Falls Reservoir and the surrounding area. Mundorff (1967) provides geologic cross sections and a description of ground water conditions within an area that includes the southern portion of the reservoir. Pierce and Scott (1982) describe alluvial-gravel deposition along the Snake River northeast of the reservoir. Houser (1992) describes the Quaternary stratigraphy of the area northeast of the reservoir and includes a plan map and cross sections.

The geologic history provided by Trimble and Carr (1961) provides an understanding of the relationship of geologic units in the vicinity of the American Falls Reservoir.

"Rocks exposed along the Snake River include rhyolitic and welded tuff of Pliocene age; basalt and basaltic tuff of probable early Pleistocene age; clay silt, sand and gravel of middle to late Pleistocene age, mostly lucustrine and fluvial;

basalt of middle to late Pleistocene age; and alluvium and dune sand of Recent age" (page 1741).

"The oldest rocks prominently exposed in the Snake River canyon are the Pliocene Neeley Lake Beds … and the Walcott Tuff… These two conformable formations crop out mainly along the south side of the Snake River from American Falls southwestward to Rock Creek" (page 1741).

"The next youngest formation… is named the Raft Formation…. The Raft is mainly light-colored poorly bedded to nearly massive silt in the upper part and tan and gray clay, silt and fine sand in the lower part" (page 1742).

"Above the Raft, but possibly intertonguing with it, is a widespread group of nearly contemporaneous basalt flows from several vents northwest of the Snake River. These flows are restricted to the northwest side of the Snake River valley… These basalts are part of what has been mapped as Snake River Basalt… Cedar Butte Basalt..., which is younger than most of the Snake River Basalt, … occurs in an area about 8 or 10 miles long by 4 or 5 miles wide, almost entirely west of the present Snake River Canyon" (page 1742).

"The American Falls Lake Beds, which were deposited immediately after emplacement of the Cedar Butte Basalt, overlie the Snake River Basalt or the Raft Formation … where the basalt is absent… Above the American Falls Lake Beds are deltaic sand and gravel deposits, and several terrace deposits of silt, sand and gravel, all mainly north and east of American Falls" (pages 1742 - 1743).

Mundorff (1967) depicts the subsurface geology of the southwestern portion of the American Falls area, based on information from water wells, in a series of cross-sections that he combined into a fence diagram. A location map and selected portions of the fence diagram are presented in Figures 5a, 5b and 5c. The following points can be drawn from the Mundorff (1967) cross sections.

- The wells in Township 7 South Range 30 East (T7S R30E 29aa1, 20da1 and 20ab1) penetrate a considerable thickness of basalt overlying sediments, shown as the Raft Formation (Figure 5b). The basalt thins considerably to the southeast as is shown by wells 7S 30E 23cc1. The American Falls Lake Beds directly overlie the Raft Formation in this area.
- The basalt penetrated in wells along the northwest side of the reservoir is thinner with basalt flows interlayered with the American Falls Lake Beds and the Raft Formation as shown by well 7S 30E 11aa1 (Figure 5c). Only limited basalt was penetrated by well 6S 31E 32cd1 near the shore of the reservoir.
- Only thin basalt layers are penetrated by wells on the southeast side of American Falls Reservoir (not shown on Figure 5).
- The Mundorff (1967) fence diagram shows that the basalt, which is thick to the northwest in the center of the plain, thins and interfingered with mostly fine-grained sediments (Raft Formation and American Falls Lake Beds) near and likely under at least the southern portion of the reservoir.

Houser (1992) provides the most complete understanding of the subsurface geologic setting of the northeast portion of the American Falls area. Lithologic logs from 240 water wells were analyzed as part of the study and used to prepare a plan map and a number of cross sections. The geologic map prepared by Houser (Figure 6) shows the mapped surface geology and the well locations. The geologic notation used by Houser (1992) is as follows: 1) the American Falls Lake beds is noted as Ql with the Raft Formation as Qr; 2) Pleistocene basalt is noted as Qby or Qb with Snake River Gravel units identified as Qb; and 3) Tertiary basalt is shown as Tb The geologic map (Figure 6) shows the locations of ten cross sections (A-A' through J-J') The geologic cross sections are based on lithologic information from well logs. Selected cross sections are reproduced as Figures 7a, 7b, 7c and 7d. The following points can be drawn from the Houser (1992) map and cross sections.

- The geologic map (Figure 6) shows that the American Falls Lake Beds (Ql) outcrops in a discontinuous pattern over a large area northeast of the reservoir and north of the Snake River.
- The northeast maximum extent of the Raft Formation in the subsurface (subcrop) is shown on Figure 6. This line trends mostly west-northeast across the Fort Hall Bottoms past the town of Springfield. Houser (1992) did not identify the Raft Formation in the subsurface any further to the northeast.
- Geologic cross sections A-A' and B-B' are oriented approximately north-south and extend into the reservoir. The cross sections show that the American Falls Lake Beds (Ql) are present near land surface over much of the area (Figure 7a). The Raft Formation sediments (Qr) underlie the American Fall Lake beds, separated in places by a basalt layer. Either gravel (Qg) or basalt (Qb) underlies the Raft Formation (Qr). The low hydraulic conductivity units, particularly the Raft Formation, are important because they likely limit the hydraulic connection between deeper ground-water flow systems and shallow ground water and the reservoir.
- Cross-sections D-D' and E-E' are oriented northwest-southeast and are located northeast of the reservoir. In cross section D-D' (Figure 7b), the Raft Formation is depicted as extending continuously under the northeast end of the reservoir, the Snake River and the southwest portion of the Fort Hall bottoms. Cross section E-E' shows the Raft Formation as laterally continuous over the area but thinner. Either gravel (Qg) or basalt (Qb) is shown as both underlying and overlying the Raft Formation in sections D-D' and E-E'. The American Falls Lake Beds is a thin, near-surface unit in both of these sections
- Cross sections F-F' and G-G' are parallel to sections D-D' and E-E' but are located up river to the northeast. The American Falls Lake beds are still present as a near-surface unit but the Raft Formation unit is missing (Figure 7c). In section F-F', the Snake River and Fort Hall Bottoms are shown to be underlain by Snake River Gravel deposits (Qg).
- Cross section I-I' trends in a southwest-northeast direction from the northeastern corner of the reservoir to north of Ferry Butte. Cross section J-J' trends from

south-southwest to north-northeast on the east side of Ferry Butte (Figure 6). Cross section I-I' shows that a thick section of the Raft Formation is present under American Falls Reservoir but missing to the northeast (Figure 7d). Houser (1992) shows that a thin clay layer is present between the Quaternary basalt (Qb) and the gravel over about half of the section. Cross section J-J' shows a thinner section of the Raft Formation in the southwest with a considerable thickness of gravel (Qb) overlying Tertiary basalt in much of the area.

- Houser (1992) shows the presence of Tertiary basalt (Tb) under the Snake River Gravel (Qb) at the southwestern (right) end of the four east-west cross sections (D-D', E-E', F-F' and G-G'). The Tertiary basalt is also shown over most of the length of cross section J-J'.
- The Houser (1992) study shows that the fine-grained sedimentary units (American Falls Lake Beds and the Raft Formation) likely are present under the northeast end of the American Falls Reservoir. The Raft Formation is not present in the surbsurface northeast of a line roughly half way between the reservoir and Ferry Butte. The gravel and basalt units likely act as unconfined aquifers northeast of the subcrop line for the Raft Formation and as confined aquifers where they are overlain by the Raft Formation.

Pierce and Scott (1982) provide a description of gravel deposits along the Snake River northeast of the American Falls Reservoir. Their plan view map is reproduced as Figure 8.

> "An extensive gravel deposit of late Pleistocene age, about 15 kilometers wide and at least 10 meters thick, occurs along the Snake River from St. Anthony to American Falls Reservoir (see Figure 8)… Two complimentary effects fostered its accumulation. First, American Falls Lake was dammed by the Cedar Butte Basalt 72,000 +/- 14,000 years ago, resulting in elevated base levels upstream until about 14,000 to 15,000 years ago when the Bonneville Flood drained the lake… Second, conditions that favored deposition in other areas of nonglacial and glacial gravels at this time also existed along the Snake River… Following the drainage of American Falls Lake and the change in stream regimen between late Pleistocene and Holocene time, this gravel fill was incised by the Snake River and its tributaries" (page 695).

The shallow gravel zones shown in the Houser (1992) cross sections near the Snake River and underlying the Fort Hall Bottoms likely are the gravel deposits described by Pierce and Scott (1982). Figure 8 shows that gravel deposits are present northeast of the American Falls Reservoir for a considerable distance beyond Blackfoot.

Summary of Geologic Setting

Four aspects of the geologic setting of the Near Blackfoot to Neely Reach of the Snake River are of particular importance with respect to ground-water flow and the hydraulic interconnection of ground water and surface water.

- The general area of the American Falls Reservoir is underlain by basalt layered with fine-grained sediments. The deposition of fine-grained sediments in this area resulted from damming of the ancestral Snake River by basalt in Quaternary time.

The spatial distribution of the fine-grained sediments, particularly the Raft Formation, provides important control on ground-water flow. The Raft Formation thins generally to the east and northeast and can be identified in the subsurface only to a line approximately half way between the upper end of the reservoir and Ferry Butte. Upward ground-water flow from basalt aquifers into the American Falls Reservoir is likely limited by the presence of the fine-grained sediments of the Raft Formation and the American Falls Lake Beds.

- Gravel associated with the Snake River is present in the subsurface approximately along the present alignment of the river starting above Idaho Falls and continuing down river to thin and terminate against fine-grained sediments near the upper end of the American Falls Reservoir. The fine-grained sediments (Raft Formation and American Falls Lake Beds) in this area effectively block southwestward movement of ground water in the shallow sediments and result in ground-water discharge in the form of springs and river gains, generally northeast of the subcrop of the Raft Formation.
- The presence of the fine-grained sediments at depth in the vicinity of the American Falls Reservoir likely also limits southwestward flow of ground water in the deeper basalt units. This results in upward ground-water flow and discharge of water in the form of springs and river gains.
- The presence of Tertiary basalt at shallow depths in the vicinity of Ferry Butte may also be important relative to controlling ground-water flow. The Tertiary basalt, if less permeable than Quaternary basalt or Quaternary gravel, would be an additional impediment to ground-water flow. Knowledge of the hydraulic properties of the Tertiary basalt is limited.

HYDROGEOLOGIC CONCEPTUAL MODEL

The Quaternary basalt near the center of the Snake Plain generally is considered to host a single, unconfined aquifer. Water producing zones within the Quaternary basalt occur mostly at flow contacts which are present at depth intervals of about 15 to 20 feet. The average hydraulic conductivity of the basalt is extremely high.

The inter-fingering of Quaternary basalt flows with fine-grained sediments in the general vicinity of the American Falls Reservoir likely creates a subsurface environment composed of individual aquifers and confining units (aquitards). The transmissivity of the subsurface in the vicinity of the American Falls Reservoir is postulated to be much lower than the transmissivity of the aquifer to the northwest where fine-grained sediments generally are absent. The hydrogeologic environment in the area northeast of the reservoir is complicated by the presence of a shallow gravel unit roughly parallel to the Snake River. An additional complication is the presence of what is mapped as Tertiary basalt underlying the Quaternary gravel in the vicinity of Ferry Butte. The role that the Tertiary basalt plays in controlling ground-water flow patterns is unknown.

The presence of the fine-grained sediments in the subsurface (Raft Formation and American Falls Lake Beds) likely acts as a restriction for southwestward ground-water flow in both the basalt and the gravel along the Snake River. This results in upward hydraulic gradients and ground-water discharge in the form of springs and river gains.

As noted by previous investigators, most of the ground-water discharge occurs in areas northeast of the reservoir above maximum reservoir level. The sedimentary units likely are present under all but the southwestern end of the American Falls Reservoir. The amount of ground water moving vertically upward through the fine-grained sediments to discharge into the reservoir is believed to be small. The southwestern end of the reservoir is believed to act as a recharge source for ground water. Leakage likely is occurring through basalt that is present in this area.

Two major sources of information are available to combine with the hydrogeologic conceptual model to develop an improved understanding of the ground-water surface water interconnection in the Near Blackfoot to Neeley reach of the Snake River: 1) the locations and temporal variations of ground water discharges (i.e. springs, reach gains) to the river; and 2) the spatial and temporal variations in ground-water levels. Information on ground-water discharges and ground-water levels is described in the following sections.

GROUND-WATER DISCHARGE CHARACTERISTICS

Ground water discharge to the Snake River in the Near Blackfoot to Neeley reach occurs both in the form of identified springs and in the form of river gains that have not been attributed to specific springs. Information on ground-water discharge in the Near Blackfoot to Neeley reach is available from a number of different sources. The following sections provide a summary of information from each specific source.

Stearns and Others (1938)

The springs in the Fort Hall bottoms are described by Stearns and others (1938, pages 137-139) as follows.

> "Springs rise at intervals for a distance of 10 miles or more along the Fort Hall bottoms and adjacent to the Portneuf River near its mouth. Most of these springs rise on the valley floor at heights of 10 to 15 feet above the river. They have a fairly uniform aggregate discharge of about 1,400 second-feet (cfs), and most of them issue from basalt which underlies the alluvium in this area. The flow and the names of 30 of the larger springs in vicinity of the American Falls Reservoir are given below (given in this report in Table 1). The locations of the stations where the flow from these springs were measured are shown in figure … (given in this report as Figure 9)."

> "The ground-water contours … indicate that the springs bordering the Fort Hall bottoms should be divided into two groups. Batise Spring, Fish Hatchery Spring, and Wide Creek, in the Portneuf Valley form one group, and Big Spring Creek, Clear Creek, and Kinney Creek, the waters of which come from the valley of the Snake River north and east of Fort Hall, form the other group."

> "In addition to these springs, 230 second-feet (cfs) of water is discharged by 13 springs in the Aberdeen-Springfield area. These springs issue from the basalt of Gibson Butte, which collects the water from under the irrigated areas to the northeast and from seepage from the Snake River. At most of the spring vents this basalt is overlain by the American Falls lake beds or by alluvium…"

"The Portneuf and Snake Rivers are also augmented by smaller springs and by inflow rising in the stream channels themselves.…. The Snake River between the mouth of the Blackfoot River and American Falls, a distance of about 30 miles, has a total gain, exclusive of surface run-off from the upper Portneuf of about 2,500 second-feet (cfs), nearly all of which is supplied by springs."

Table 1 Spring Discharge Values Reported by Stearns and others (1938)

Number	Name	Discharge		Number	Name	Discharge
1	Rich	18.6		16	Artesian	5.5
2	Johannes	7.2		17	Sterling	6.2
3	Thorn	20.2		18	Colburn	3.2
4	Log Cabin	34.9		19	Ruger	23.9
5	Indian No. 1	47.4		20	Davis	
6	Indian No. 2	21.9		21	Franklin	
7	Indian No. 3	163.5		22	Big Jimmy	37.6
8	Indian No. 4	3.8		23	Big Spring	448.0
9	Indian No. 5	19.3		24	Kinney	29.3
10	Pyle	14.0		25	Clear	130.0
11	McTucker	26.4		26	Ford	7.4
12	Hull	7.1		27	Pocatello City	
13	Tanner	2.2		28	Batise	50.0
14	Crystal	32.8		29	Fish Hatchery	75.0
15	Danielson	51.1		30	Wide	60.0

Stearns and others (1938) discuss the possible sources of inflow to the Snake River in the reach in question. Approximate water balances are prepared for the three identified sources: 1) ground-water flow down the valley of the Portneuf, 2) precipitation on the lava beds north of the Snake River and 3) underflow along the Snake River. Stearns and others (1938, pages 141 and 142) note the following.

"Thus it appears evident that the springs in the Fort Hall bottoms are mainly supplied by this great underflow of the Snake River Valley. Coarse clean gravel deposits and basalt suitable for the accumulation of ground water underlie the river and the irrigated tracts upstream from the springs, but near Blackfoot the gravel deposits grade into relatively impermeable lake-bed silts and clays of the American Falls Basin. As a consequence the ground water that is carried by the gravel deposits tends to be forced into the basalt, which is the only available material of sufficient permeability, and practically all the springs issue from basalt."

Mundorff (1967)

Mundorff (1967) spends a number of pages dealing with a water-budget analysis of the American Falls reservoir reach. He reports the following relative to early flow measurements of the inflow (page 24).

> "Continuous records of flow in the Snake river at the two gaging stations used in the analysis are available only since 1911. Spring inflow at earlier dates can be obtained only by analysis of earlier miscellaneous records. Discharge measurements were made at different places along the Snake River in the vicinity of the American Falls Reservoir reach between 1902 and 1910. By estimating inflow from some tributaries, gains and losses in several reaches, and evapotranspiration losses from the reservoir reach, rough estimates of spring discharge were made for a period in August in three different years. These estimates are 2,000 cfs …in 1902; 1,840 cfs … in 1905 and 1,830 cfs in 1908. Although the records are incomplete and the quantities determined may be considerably in error, the records do indicate that spring inflow in the reach was considerably less before 1908 than in the years since 1911."

Mundorff (1967) presents calculated ground-water inflow to the American Falls reach of the Snake River on an annual basis from 1911 through 1960. The variability in his calculated inflow rates is small with a maximum of 2,055 cfs in 1952 and a minimum of 1,654 in 1916. The range in values from 1940 to 1960 is smaller with a minimum of 1,830 in 1956. Mundorff (1967, page 28) shows that a positive correlation exists between the calculated ground-water inflow to the American Falls reach and the 5-year progressive average of irrigation diversions to the area above American Falls Dam. Mundorff (1967, page 45) states the following in his conclusions.

> "Ground-water inflow in the American Falls Reservoir reach was probably about 1.2-1.4 million acre-feet a year (1,700-1,900 cfs) before irrigation began in eastern Idaho. Inflow increased with the increasing diversions of surface water to land adjoining the Snake River and in the late forties and early fifties averaged about 1.95 million acre-feet annually (2,600 cfs). About 1952 increased withdrawals of ground water apparently became large enough to prevent further increases of ground-water inflow. Between 1922 and 1952 the ground water inflow increased roughly 2.5 acre-feet for every 10 acre-feet of surface water diverted to lands on the Snake River Plain upstream from American Falls Dam."

Mundorff (1967) shows that his calculated monthly ground-water inflow to the American Falls reach correlates reasonably well in the period of 1952 to 1960 with water levels in a shallow well (46-feet deep) located in section 27 of township 5 south and range 31 east. A well driller's report for this well is not available on the IDWR website but other wells in this section penetrate basalt in the depth range of about 20 to about 60 feet.

Balmer and Noble (1979)

Balmer and Noble (1979) present an analysis of the water resources of the Fort Hall Indian Reservation. The study included measurement of water levels in wells and discharge from springs in the Fort Hall Bottoms. The mean flow of major springs on the

Fort Hall Bottoms, as compiled by Balmer and Noble (1979, page 17) is presented in Table 2. Some of the springs identified in Table 2 are the same as included in Table 1 from Stearns and others (1938). It is impossible to know whether flow measurements were taken at the same locations.

Table 2 Discharge of Major Springs on the Fort Hall Bottoms (Balmer and Noble, 1979)

Station	Mean flow in cfs
Hatchery Springs	103
Diggie Creek	263
Jeff Cabin Creek	21.1
Spring Creek	466
Big Jimmy Creek	30.5
Clear Creek	134
Kinney Creek	28.1
Wide Creek	57.4
Jimmy Drinks - East	103
Jimmy Drinks - West	35.4
Ross Fork	58.4

The Balmer and Noble (1979) study includes development of a water budget for the Fort Hall Bottoms. The graphical depictions of their water budget are reproduced as Figures 10A and 10B, a Snake River portion and a Portneuf River portion.

- The Snake River discharge of 4,800 cfs below the Blackfoot River (Near Blackfoot gage) increases to 5,450 cfs where it discharges into the American Falls Reservoir (Figure 10A). About 184 cfs of the total gain of about 650 cfs is noted as “groundwater to channel”. The remaining gain is from identified sources with the largest being Diggie Creek at 263 cfs.
- The Portneuf River flow increased from 270 cfs at the USGS Pocatello gage to 1,744 cfs where it discharges into the American Falls Reservoir (Figure 10B). Specific springs and creeks make up much of the gain. The combined flow of Spring Creek and Jimmie Creek (496 cfs), Clear Creek (134 cfs), Ross Fork (55 cfs), Jimmie Drinks (103 and 35 cfs) plus Wide Creek (57 cfs) is 880 cfs. Unmeasured ground-water inflow makes up an additional 428 cfs.
- Balmer and Noble (1979, page 18) note that the total identified gain to the rivers is about 2,100 cfs. Almost 70 percent of this gain is discharge to the Portneuf River with slightly less than 30 percent of the gain discharging into the Snake River.

Balmer and Noble (1979, page 156) established several temporary gaging stations to quantify inflow to the lower Portneuf River. One station was established at the Michaud Pumping Station near Siphon Road with a second station about one-half mile below Jimmy Drinks East Branch. The approximate locations of these stations are shown on Figure 10B. Six sets of measurements were obtained (dates not given). The river gain was about 619 cfs in this reach with 398 cfs accountable by individual spring inflows. Several measurements near the mouth of the Portneuf River were made during the low water period of 1977 (September 29 and November 1). The measurements indicated river gains of 671 and 637 cfs in the reach below Jimmy Drinks East Branch and the mouth. Discounting the flows in the three measured springs, the unaccounted for gain was 156 and 120 cfs for the two dates.

Kjelstrom (1995)

Kjelstrom (1995, page C17) provides the following summary of information on the gain between the Near Blackfoot and Neeley gages.

> "The Snake River gained about 1.9 million acre-ft of ground-water, largely from springs, between the gaging stations near Blackfoot and Neeley … in water year 1980. Annual streamflow gains in the reach varied little during water years 1912-80… The mean gain from ground water from 1912 to 1980 was 1.8 million acre-ft, or 2,540 ft^3/s; the standard deviation was 80,000 acre-ft, or 110 ft^3/s."

The reservoir was drawn down for dam reconstruction in 1977, providing an opportunity for measurement of the Snake and Portneuf Rivers upstream and downstream from major springs. Kjelstrom (1995, page C18) reports that the total streamflow gain from ground water in the Blackfoot to Neeley reach was estimated to be 2,560 cfs and 2,570 cfs on September 8 and 28, 1977 respectively.

Kjelstrom (1995, page C18) notes that ground-water discharge to the natural channel of the Portneuf River is about 65 percent of the total ground-water discharge to the Blackfoot to Neeley reach. He describes field measurements as follows.

> "Streamflow measurements of the Portneuf River at Pocatello and upstream from Bannock Creek were made on September 9 and 17, 1977. After these measurements adjusted for a measured diversion and estimated surface-water inflow, the average difference between outflow (measured at the downstream gage) and inflow was 1,650 ft^3/s (assumed to be ground-water discharge)".

Kjelstrom (1995), page C21) says that springs issuing from basalt north of the Snake River and American Falls Reservoir discharge about 200 cfs. The largest of these springs is tributary to Danielson Creek. Kjelstrom (1995, page C23) shows that temporal variations in discharge in Danielson Creek correlate well with water-level elevations in well 5S 31E 27aba1 (using data from 1980-81). This is the same well that Mundorff (1967) used to correlate with his calculated ground-water discharge to the American Falls Reservoir reach.

Hortness and Vidmar (2003)

Hortness and Vidmar (2003) present the results of seepage studies that were conducted jointly by the U.S. Geological Survey and the Idaho Power Company for three reaches of the Snake River: 1) lower reach from Minidoka to King Hill, 2) middle reach

from Shelley to Minidoka and 3) upper reach from Ashton to the mouth of the Henrys Fork and Snake River from Heise to Shelley. The seepage studies were conducted in 2001 and 2002. The approach used by Hortness and Vidmar (2003) is described below.

> "Data collected in each reach included discharge values from the USGS and/or IPCo (Idaho Power Company) gaging stations, discharge values at several intermediate locations obtained using acoustic Doppler instrumentation … and measured and/or inspected discharge values for several miscellaneous inflows (mostly tributaries) along the entire length of each reach obtained by field personnel" (page 1).

The Near Blackfoot to Neeley portion of the middle reach of the Snake River was divided into three subreaches using four gaging sites (Figure 11). Station M9 at the upper end of the reach is the USGS stream gaging station entitled Snake River near Blackfoot. Station M12 at the lower end of the reach is the USGS stream gaging station entitled Snake River at Neeley. Acoustic Doppler discharge measurement data were taken at two intermediate stations: M10 – Snake River near Pingree; and M11 – Snake River above McTucker Creek near Pingree. Additionally, measurements or observations were taken at a number of tributaries within the reach. The seepage studies were done twice in 2001 and three times in 2002.

Appendix B of the Hortness and Vidmar (2003) report include tables of discharge data for each of the four stations (discharge readings were not obtained from stations M10 and M11 for all of the seepage runs) plus estimates of selected inflows between the stations and changes in storage in American Falls Reservoir. Table 3 provides a summary of the seepage run results in cfs. Figure 11 shows the seepage run results for the April 9-10, 2002 data collection effort.

Figure 11 show a gain of 460 cfs from station M9 (Near Blackfoot gage) to M11 (head of the reservoir) with a 1,232 cfs gain over the length of the reservoir (station M12 minus station M11). The Hortness and Vidmar (2003) data in Table 3 show a range of stream flow gains of 1,390 to 2,186 cfs from the Near Blackfoot gage (M9) and Neeley gage (M12). The largest calculated gain was in November 2002 with the smallest in July 2002.

The study results shown on Table 3 are different from the results provided in the Hortness and Vidmar (2003) because two errors were discovered in the original document. The first error is in the calculated inflow between stations M11 and M12 for the July 23-24, 2002 seepage run. Two sites are included in estimated inflow for the July 2002 calculations that are not included in analysis of the other four seepage runs. The inflow for the other four seepage runs between stations M11 and M12 is the sum of discharge at the following sites (Hortness and Vidmar 2003, Table B20).

- Portneuf River near Tyhee
- Bannock Creek near Michaud
- Aberdeen Waste Drain near Aberdeen
- Tarter Waster near American Falls
- Seagull Bay near American Falls
- Falls Irrigation Pump near American Falls

Table 3 Summary of Seepage Run Results (cfs) (Hortness and Vidmar, 2003)

Station	April 3-6, 2001	Oct 31-Nov 1, 2001	April 9-10, 2002	July23-24, 2002	Nov 5-6, 2002
M9	2,190	1,810	1,750	3,960	2,060
Est. Inflow	0	0	0	0	0
Est. Outflow	0	0	0	0	0
M10	2,520	2,410			2,430
Est. Inflow	0	0	0	0	0
Est. Outflow	0	0	0	0	0
M11	2,820		2,190		2,550
Est. Inflow	588	481	538	246	421
Est. Outflow	0	0	0	96	0
Res. Storage	800	4,000	2,300	-4,900	4,300
M12	3,920	354	1,660	10,400	367
M10-M9	**330**	**600**			**370**
M11-M10	**300**				**120**
M12-M11	**1,312**		**1,232**		**1,696**
M12-M10	**1,612**	**1,463**			**1,816**
M12-M9	**1,942**	**2,063**	**1,672**	**1,390**	**2,186**

The following two additional sites are included by Hortness and Vidmar (2003) in the calculated inflow between stations M11 and M12 for the July 23-24, 2002 seepage run.

- McTucker Creek Springfield
- Danielson Creek near Springfield

The calculated inflow for the July 23-24, 2002 seepage run is reported in Table B13 of Hortness and Vidmar (2003) is 246 cfs rather than 506 cfs if the two additional stations are not included (see Table 3). Table B13 and Figure B5 in Hortness and Vidmar (2003) show a streamflow gain of 1,131 cfs from the Near Blackfoot gage to the Neeley Gage (M9 to M12). This number is not comparable to the other reach gains presented in the

report because of the inclusion of the two additional sites in the calculated inflow between stations M11 and M12. The corrected calculated gain is 1,390 cfs.

The second error is in the calculated reach gain from M11 to M12 for the November 5-6, 2002 seepage run. As is shown on Table 3, the gain between the Near Blackfoot and the Neeley gaging stations (M9 and M12) was 2,186 cfs. Table B17 and Figure B5 of the Hortness and Vidmar (2003) report show this gain as occurring between M11 and M12 rather than M9 and M12. The correct gain across the American Falls Reservoir (M12-M11) for the November 2002 seepage run is 1,696 cfs.

Hortness and Vidmar (2003) obtained flow measurements at 18 surface water sites that discharge directly into the American Falls Reservoir. Seven of the sites, including the Portneuf River and Bannock Creek, are included in their inflows in the M11 to M12 reach (Table 3). The total discharge of these seven sites ranges from a low of 246 cfs in July 2002 to a high of 588 cfs in April 2001. The eleven remaining surface water sites are: 1) Ross Fork, 2) Clear Creek, 3) Spring Creek, 4) McTucker Creek, 5) Danielson Creek, 6) Sterling Waste, 7) Spring #1 Sterling, 8) Crystal Spring, 9) Spring #2 Sterling, 10) Spring #3 Sterling and 11) Spring Hallow. The combined discharge of these sites was 541.5 cfs in October-November 2001, 634 cfs in July 2002 and 604 cfs in November 2002. Not all of the sites were measured in April 2001 and April 2002. Table 3 shows that the calculated gain across the American Falls Reservoir (M12-M11) was 1,696 cfs in November 2002. Thus, the eleven additional measured inflows to the reservoir (604 cfs) account for about 36 percent of the calculated gain in the American Falls Reservoir reach in November 2002. Most of the remainder of the calculated gain likely is discharge from the spring-fed creeks described by Balmer and Noble (1979) and Kjelstrom (1995) that discharge to the lower Portneuf River. The presence of the sedimentary formations (American Falls Lake Bed and Raft Formation) makes it difficult for large quantities of water to discharge directly into the bottom of the reservoir.

IDWR Reach Gain/Loss Program (2006)

The IDWR Reach Gain/Loss Program is used to develop estimates of historical river gains and losses for various reaches. Cosgrove and others (2006) describe the program as follows.

> "The Reach Gain/Loss Program uses gaged reach inflows and outflows, measured diversions and estimated irrigation returns and reservoir storage and evaporation to calculate a (monthly) water balance for the reach. The residual of the water balance is the estimated river reach gain from or loss to the aquifer" (page 92).

Most of the ground-water discharge to the Snake River occurs in two reaches: 1) Milner to King Hill and 2) Near Blackfoot to Neeley. Cosgrove and others (2006) present calculated average annual river gains in these reaches starting in the early 1900's. A plot of these data is presented in Figure 12. Their description of the temporal pattern of discharge in these two locations is presented below.

> "Natural discharge from the Snake River Plain aquifer is primarily to the Snake River along two reaches: Kimberly to King Hill and Near Blackfoot to Neeley … Spring discharge has varied in response to changes in precipitation, irrigated acreage, and irrigation practices. Overall, discharge in the Kimberly to King Hill

reach appears to have been impacted more than in the Near Blackfoot to Neeley reach…Historically, aquifer water levels and corresponding discharges to the Snake River rose significantly at the onset of surface water irrigation. This is particularly apparent in the historic discharge in the Milner to King Hill reach… Aquifer water levels peaked about 1950 and have been declining since that time. The declines are attributed to the onset of ground-water irrigation, more efficient surface water irrigation practices such as conversion to sprinkler irrigation and canal lining, and the recent seven years of drought. Historic discharge in the Near Blackfoot to Neeley reach shows a less dramatic response to historic changes in irrigation practices, however the reach does exhibit more dramatic seasonal variation since the 1950s" (pages 15-16).

Monthly average river gains, calculated using the IDWR Reach Gain/Loss Program, were obtained from Wylie (2007). The calculated monthly river gains from Near Blackfoot to Neeley results (Figure 13) show a greater data scatter than the annual gains shown on Figure 12. There are some longer-term trends in the river gain with a high in about 1987, a low in about 1995, a high in about 2000 and a low in 2006 that continues into 2007. The average calculated river gain for the reach decreases with time as follows: 2,559 cfs for the period of January 1970 through August 2007, 2,341 cfs for the period of January 2000 through August 2007 and 2,104 cfs for the period of January 2001 through August 2007.

TEMPORAL WATER-LEVEL PATTERNS IN WELLS

The comparison of temporal water-level data from wells from within the basalt-dominated portion of the Snake Plain aquifer to wells near the Near Blackfoot to Neeley reach of the river provides information of hydraulic connection of the ground-water systems. The water-level data were obtained from the U.S. Geological Survey web site.

Hydrographs for selected single completion wells (Figure 14) are presented in Figures 15 through 19. The order of presentation starts with wells completed in basalt north of American Falls Reservoir followed by wells located nearer the reservoir.

- Wells 2N 31E 35dcc1 and 1S 30E 15bca1 (Figure 15) have similar hydrographs and represent the temporal water-level pattern that is typical of the basalt portion of the Snake Plain aquifer northwest of the Near Blackfoot to Neeley reach. Both wells are deep (636 and 751 feet) and the static depth to water is considerably below land surface (594 and 721 feet in 2007). Both wells show a downward overall water-level trend with recent highs in November 1984 and January 1999 and recent lows in August 1981 and August 1994. The water-level rise between August 1981 and November 1984 was about six feet. The seasonal water-level changes in both wells were generally less than two feet with seasonal lows in late spring or summer and seasonal highs in late fall or winter.
- Wells 2S 32E 23bbb1 and 4S 31E 20bbb1 (Figure 16) show a similar water-level pattern as the previous pair of wells. These two wells are 194 and 201 feet deep and have water levels about 171 and 127 feet below land surface. The water-level rise between August 1981 and November 1984 was about five feet in both wells. There is more seasonal scatter in the data points in these wells as compared to wells to the north, probably related to pumping and irrigation application. The

seasonal water-level changes in both wells were generally less than two feet with seasonal lows in spring and seasonal highs in fall.

- Wells 4S 31E 36aba1 and 5S 31E 27aba1 (Figure 17) are both shallow (17 and 51 feet) located in areas irrigated using surface water. The wells show a rapid response to surface water irrigation practices. There is considerable scatter to water-level in both wells with lower water levels in the spring and higher water levels in the fall. The water-level rise from 1981 to 1984, noted in the wells to the north, is not evident in the data from these two shallow wells. The water-level elevation in both wells was lowest in the period of record in 2004-2005.
    - For well 4S 31E 36aba1, the annual water level fluctuation was five to seven feet with no long-term pattern of water-level change from the start of records through the mid 1970's. There is a significant change in the water-level pattern in well 36aba1 starting in about 1978 with lower water level highs and less annual water-level change. Care must be taken to differentiate changes in water-level patterns from apparent changes caused by decreases in frequency of measurement or changes in dates when measurements were taken. The data show a pattern of water-level decline with several multi-year trends (low in 1993 and high in 1999). The water level pattern seen in well 36aba1 is a reflection of change in surface water irrigation practices in the area (such as change from gravity to sprinkler irrigation or lining of canals) and possibly the impacts from ground-water pumping.
    - The overall pattern of the hydrograph for well 5S 31E 27aba1 is similar to well 4S 31E 36aba1 except for larger annual water-level fluctuations. The annual water-level fluctuation was up to 15 feet in the 1950's and 1960's. The range in annual water-level changes lessened (less than nine feet) in the mid 1970's and 1980's with both lower highs and higher lows. Again, some of the change in water-level pattern is from changes in the frequency and/or timing of measurements. An overall downward trend in water levels is evident in the record starting in the early 1980's. The water-level pattern in this shallow well likely is a combination of impacts from changes in surface water irrigation practices and possible impacts from ground-water pumping.
- Well 6S 31E 16bab1 (Figure 18) is located near the northwest shore of American Falls Reservoir. The hydrograph for this 134-foot well has characteristics of the nearby two shallow wells (Figure 17) and the deeper wells to the north (Figures 15 and 16). Seasonal water-level changes were less than about five feet in the 1950's and 1960's, except for scattered low water level readings. According to the USGS record for this well, the pump in the well was operating when the scattered low water-level readings were taken.
- Well 2S 34E 33bba1 (Figure 19) is located near the Aberdeen-Springfield Canal northeast of the American Falls Reservoir. This is 40 feet deep and has high water levels in the fall and low water levels in the spring, which is typical of surface water irrigated areas. The seasonal water-level change generally is five to

six feet. The hydrograph for well 33bba1 is similar to the shallow wells shown on Figure 17. The most likely causes for the water-level pattern in well 33bba1 are changes in surface water irrigation practices in the area and possible impacts from ground-water pumping.

A number of locations have clusters of wells completed to different depths. These wells allow characterization of vertical hydraulic gradients and temporal changes in water-level elevation with depth. Water-level data are available for these wells since about 1980. The locations of the wells are shown on Figure 14.

- Wells 4S 32E 1cba1, 1cba2, 1cba3 and 1cba4 are constructed to depths of 90, 53, 242 and 433 feet respectively and are located near the Aberdeen-Springfield Canal at a site north of the northeast end of the American Falls Reservoir (Figure 14). The water-level patterns for the two shallow wells (Figure 20) are similar with seasonal changes of about 7 to 9 feet and lows in the spring and highs in the fall. The seasonal changes are likely from surface-water irrigation activities. The two deeper wells have much smaller seasonal changes. Figure 20 shows that there was an upward hydraulic gradient between the two deeper completions from the start of the record through about 2002 when the wells had about the same water-level elevation. The scatter in data for the 242-foot well starting in 2005 is difficult to explain. The overall water-level pattern, evident in the three wells with long-term records likely stems from a combination of changes in surface-water irrigation practices in the area and impacts from ground-water pumping.
- Wells 4S 33E 20cbb1, 20cbb2, 20cbb3 and 20cbb4 are located northeast of American Falls Reservoir near the Snake River and are completed at depths of 62, 108, 365 and 738 feet (Figure 14). An upward vertical gradient is evident from the water-level data from all four of these wells (Figure 21). The water-level elevation in the 108-foot well is about 10 feet higher than in the 62-foot deep well. These data indicate an upward vertical gradient of about 0.2 ft/ft. The upward gradient persists deeper in the section but is smaller. The long-term water-level pattern in the 738-foot well is typical of the basalt aquifer to the northwest. This well has one to two feet of seasonal water-level changes with water-level highs generally in early winter and water-level lows in July. This well likely reflects the seasonal impacts of ground-water pumping. The long-term water-level pattern in the 365-foot well is dissimilar from any of the other hydrographs in the area with a high water-level elevation in November 1989 and very small seasonal fluctuations. Reasons for the uniqueness of the hydrograph for the 365-foot well are unknown. The hydrograph for the 108-foot completion has considerable seasonal variation but does not fit the seasonal patterns of other shallow wells in areas of irrigation by surface water. Several significant water level changes (such as 4.5-foot drop between January and March 1992 and a 3.7-foot drop between January and March 1998) are difficult to explain. There are about two-feet of seasonal water-level change in the 62-foot completion well; water-level highs are either in May or September, probably reflecting high river conditions in May and surface-water irrigation impacts in September.
- Wells 4S 33E 25ddb1-2 and 4S 34E 8dbd1-3 are located south of the Snake River and between Ferry Butte and the American Falls Reservoir (Figure 14). Wells

25dbb1 and 25dbb2 have completions at depths of 21 and 117 feet and are located is down gradient (southwest) of wells 8dbd1, 8dbd2 and 8dbd3 which have completions at depths of 38, 99 and 232 feet. Water-level data for these wells are only available during the period of 1985 to 1994 (Figure 22). The water-level data from the 21 and 117-foot completions at 4S 33E 25ddb show an upward vertical gradient of about 0.2 ft/ft with a greater rate of decline during the period of record in the 117-foot completion than in the 21-foot completion. The three completions at 4S 34E 8dbd also show upward ground-water flow but the vertical gradient is smaller (about 0.05 ft/ft). The declining water-level trend in all five of these wells is consistent with this period of record for other wells in the area. The 232-foot completion at 25dbb has a consistent seasonal water-level pattern with low levels in late spring and a high in early winter. A consistent seasonal trend is not as identifiable in the other wells.

- Wells 3S 34E 22dab1 and 22dab2 are located northeast of Ferry Butte and are completed at depths of 85 and 569 feet (Figure 14). Limited water-level data for the 569-foot well are similar in pattern to the 85-foot well with a small downward hydraulic gradient (Figure 23). The overall water-level pattern in both wells is similar to that found in the Snake Plain aquifer to the northwest. The 569-foot well has a seasonal fluctuation of about two to three feet with low water levels in the winter and spring and high water levels in the fall. The 85-foot well has a similar seasonal range in water levels with high water levels generally in the fall.
- Wells 2S 35E 11ddd1-4 are located north-northeast of the City of Blackfoot and are completed at depths of 97, 376, 570 and 682 feet (Figure 14). Note that the scale on the right side of the Figure 24 is for well 11ddd1 (97-foot completion) is three times the range for the other three wells. The hydrograph for the 97-foot well (11ddd1) shows very large seasonal water-level changes (35 to 50 feet), water-level highs and lows that are consistent with surface-water irrigation effects and does not have long-term pattern of water-level decline. There is a downward hydraulic gradient of about 0.18 ft/ft from the 97-foot well to the 376-foot well. The deeper wells at this site have a water-level pattern that is similar to wells located north of American Falls Reservoir with a fairly large seasonal water-level change (three to seven feet). An upward hydraulic gradient was present from the 682-foot completion to the 376-foot completion in the early 1980's. However, these two wells show a downward hydraulic gradient based on the few data points in 2001 and 2002.

Mundorff (1967) notes that shallow wells respond to the large annual range in lake stage only near the southwest end of the American Falls Reservoir. The locations of wells identified by Mundorff (1967) as responding to reservoir stage are shown on Figure 25. A temporal plot of reservoir stage and water-level elevations for one of the wells (7S 30E 24ddc1) for a period of time in the 1960's is presented in Figure 26. The plot shows that the water-level in the well is lower than the surface water at high reservoir stage and higher than the surface water at low reservoir stage. Leakage of water from the west end of the reservoir is likely related to basalt present near land surface in this area.

Geologic Controls for Ground-Water Discharge

Ground water discharges in an area northeast of the American Falls Reservoir because of changes in geology that result in lower aquifer transmissivity in this area. The gravel zone that hosts a shallow ground-water flow system along the Snake River essentially terminates against the fine-grained sediments of the American Falls Lake Beds and the Raft Formation. In the same way, basalt that makes up most of the Snake Plain aquifer occurs only as individual flows within a sequence of mostly fine-grained sediment. The lower transmissivity in the immediate vicinity of the American Falls Reservoir acts similar to a subsurface dam and results in ground-water levels at or above ground surface in shallow aquifers northeast of the reservoir. Springs occur in these areas. There is also a significant upward hydraulic gradient which indicates ground-water flow occurs from deeper aquifers to shallow aquifers and then to discharge locations.

Studies by Balmer and Noble (1979) and Kjelstrom (1995) plus other authors are sufficient to conclude that the vast majority of ground-water discharge occurs upstream of the American Falls Reservoir, probably controlled by the subcrop of the Raft Formation. The amount of ground-water discharge directly into the bottom of the reservoir is unknown but believed to be small.

Estimation of Ground-Water Discharge

The amount of ground-water that discharges to the Snake River in the Near Blackfoot to Neeley reach has been estimated by a number of investigators using a variety of direct measurement and mass balance approaches. The mass balance approach involves measurement of the flow in the river at an upstream site (often the Near Blackfoot site) and subtracting that number from the flow in the river at a downstream site (often below the American Falls Dam at the Neeley site) and adjusting for known inputs and known outputs. Changes in storage within the American Falls Reservoir are also taken into account. The accuracy of the calculated river gain depends on the accuracy of flow measurements and the detail taken in accounting for all inputs and outputs and the change in storage in the reservoir.

The following sections describe the results of the selected investigation efforts.

- Studies conducted by Balmer and Noble (1979) are particularly important because flow measurements were obtained on a large number of springs and tributary streams near the northeast end of the reservoir. Their studies, conducted in the late 1970's, indicate that the Snake River gains about 650 cfs from the Near Blackfoot gage to the reservoir with about 70 percent of the gain from documented sources (individual springs and creeks) and 30 percent from ground-water discharge to the channel. Balmer and Noble (1979) calculated a gain in the Portneuf River from the Pocatello gage to the reservoir of about 1,470 cfs with about 70 percent from documented sources and about 30 percent from ground-water discharge to the channel. This gives a total gain to the rivers of about 2,100 cfs (rounded to two significant digits). Kjelstrom (1995, page C21) says that springs issuing from basalt north of the Snake River and American Falls

Reservoir discharge about 200 cfs. The largest of these springs is tributary to Danielson Creek. Combining the two sources of information, the estimated ground-water discharge to the Snake River in the Near Blackfoot to Neeley reach in the late 1970's was about 2,300 cfs.

- Kjelstrom (1995, page C17) used data from U.S. Geologic Survey stations, measurements of diversions and return flows and changes in reservoir storage to calculate ground-water discharge in the reach using the mass balance approach. He reports the mean gain from ground water between the Near Blackfoot and Neeley from 1912 to 1980 was 2,540 cfs with a standard deviation of 110 ft^3/s.
- The Hortness and Vidmar (2003) seepage run data in a mass balance approach show a range of streamflow gains of 1,390 to 2,186 cfs from the Near Blackfoot gage (M9) and Neeley gage (M12). The largest calculated gain was in November 2002 with the smallest in July 2002.
- The average calculated river gains for the reach for different time periods using the IDWR Reach Gain/Loss Program are as follows: 1) 2,559 cfs for the period of January 1970 through August 2007, 2) 2,341 cfs for the period of January 2000 through August 2007 and 3) 2,104 cfs for the period of January 2001 through August 2007. These values show that the calculated river gains have decreased with time.

Relationship of Ground-Water Levels and Ground-Water Discharge

As with any ground-water system, temporal variations in the discharge from springs in the Near Blackfoot to Neeley reach of the Snake River are related to water-level changes in the source aquifer. Higher discharge from the springs occurs because of higher ground-water levels. The converse is also true. The relationship of ground-water levels to ground-water discharge is described in this section using a well located near Aberdeen and several wells located northeast of the reservoir as compared to calculated ground-water inflow and the discharge of Spring Creek.

Mundorff (1967) compared his calculated monthly values of ground-water inflow to American Falls Reservoir to well 5S 31E 27ab1, located north of Aberdeen (Figure 14). As Mundorff shows (Figure 27), the water-level pattern in the well, which responds to surface irrigation in the area, is similar to the temporal pattern of calculated ground-water inflow to the reservoir.

Water-level data from well 5S 31E 27aba1 (the same well used by Mundorff) are plotted with the monthly reach gains calculated using the IDWR Reach Gain/Loss Program in Figure 28. The seasonal range in water levels in the well was about 15 feet in the 1950's and 1960's and decreased to less than nine in the mid 1970's and 1980's with both lower highs and higher lows. The seasonal range in water levels has been less than seven feet since about 1990. An overall downward trend in water levels is evident in the record starting in the mid 1980's although the frequency of measurement also decreased starting in the late 1980's. Ground-water levels in well 5S 31E 27aba1 show a similar pattern as the calculated reach gain starting about 1990. The drop in water level in the well after about 1998 is very similar to the decrease in the calculated river gain in the same period. The water-level pattern in this shallow well likely is a combination of

impacts from changes in surface water irrigation practices and possible impacts from ground-water pumping. This suggests that the decrease in calculated gains using the IDWR Reach Gain/Loss Program also is a result of the combined impacts of changes in surface water irrigation practices and possible impacts from ground-water pumping.

The analysis of the discharge of Spring Creek with ground-water levels in the area provides an additional opportunity to understand the relationship between ground-water levels and ground-water discharge. Spring Creek heads in a group of springs located west of Ferry Butte and is fed nearly all from ground-water discharge. According to Nathan Jacobson of the U.S. Geological Survey (Jacobson, 2008), the contribution of irrigation return flow to Spring Creek during the irrigation season is a small part (less than 5%) of the total flow. Figure 29 shows the locations of the gaging station on Spring Creek, the springs near Ferry Butte that are the primary source for the stream flow and the locations of nearby observation wells.

The temporal pattern of the discharge of Spring Creek is shown in Figure 30 along with water-level elevations in well 4S 33E 20cbb1. Well 4S 33E 20cbb1 is the shallowest (62 feet) of four wells of various depths that are located about four miles west-northwest of the gaging station location on Spring Creek and about seven miles southwest of the primary springs that feed the stream near Ferry Butte. Daily discharge data are available from the U.S. Geological Survey station Spring Creek at Sheepskin Road starting in the early 1980's. The multi-year temporal changes in the Spring Creek discharge are very similar to the long-term hydrograph for well 20cbb1. There is a high in the mid 1980's, a low in the mid 1990's, a high in the late 1990's and then the lowest discharge and water level in the period of record in 2004-2005. The seasonal features in the two records are harder to correlate, in part because of the different frequency of data points (daily for the creek and every other month for the well). In Figure 30, well 4S 33E 20cbb1 has a seasonal change of about two feet for most of the period of record with highest water levels in the fall. The seasonal water-level pattern in the well appears to change significantly in the period of March 2001 to March 2003 (almost no seasonal water level changes). Reasons for this change are unknown.

The discharge pattern for Spring Creek is compared with hydrographs of two clusters of wells located on the southeast side of the Snake River (the nearest observation wells with temporal records to the gaging station and springs) in Figure 31. Wells 4S 33E 25ddb1 and 25ddb2 are located less than a mile southeast of the Spring Creek gaging station (Figure 29). Both wells are shallow with depths of 117 and 21 feet. Wells 4S 34E 8dbd1, 8dbd2 and 8dbd3 are located south of Ferry Butte and about one mile from the springs that are the primary source of water for Spring Creek. Well depths are 232 feet, 98 feet and 38 feet respectively. Water-level data for these wells are available only from 1985 to 1994. The seasonal change in water levels is small in all five of these wells. The lack of significant seasonal water-level changes fits with the locations of the wells away from irrigated lands and near a ground-water discharge area. The downward water-level trend in the wells is similar to that shown for well 4S 33E 20cbb1 on Figure 30 and correlates with the discharge record from Spring Creek.

The variations in discharge pattern of Spring Creek during on a calendar-year basis over the period of record provide important information relative to ground-water levels and possible causes for changes in both ground-water levels and spring discharge.

Complete year discharge records are available for Spring Creek for the years 1981 through 2007. Figure 32 presents the flow data as average discharge for five-year periods (1981-1985, 1986-1990, 1991-1995, 1996-2000, 2001-2005) and the average of years 2006 and 2007. The entire discharge record for Spring Creek is shown on Figure 30.

- The calendar-year plot of average daily flow of Spring Creek during the period of 1981-1985 (Figure 32) shows a low of 344 cfs on January 1st and July 9th and a high of 414 cfs on October 11th. The discharge steadily increased from the low in July to the high in October with a gradual decrease through the end of the year.
- The average daily flow of Spring Creek during the period of 1986-1990 varied from a low flow of 340 cfs on July 7th to high flows of 390 cfs on May 31st and 387 on October 6th (Figure 32). The flow-rate pattern in 1986-1990 is similar to 1981-1985 except for the lack of a higher peak in the fall.
- The pattern of average daily flows of Spring Creek in 1991-1995 was similar to previous five-year periods only the discharge magnitude was considerably lower. The low flow was 301 cfs on July 9th with high flow rates of 354 cfs on June 6th and 356 cfs on October 7th.
- The 1996-2000 time period includes several years of higher stream flow including the peak flow in the period of record at 605 cfs on June 8, 1998 (Figure 30). The average daily flows of Spring Creek for the 1996-2000 time period (Figure 32) were similar to the 1981-1985 and 1986-1990 periods in shape and magnitude except for the spring high flow period. The average daily high flow value was 419 cfs on June 8th with an average daily low of 337 on July 25th.
- The 2001-2005 time period has much lower average daily discharges than any of the four preceding five-year periods. The average daily high flow was 314 cfs on January 1st with an average daily low flow of 253 cfs on July 3rd.
- The average daily flow of Spring Creek during calendar years 2006 and 2007 are lower than any of the preceding five-year averages with the exception of several short periods. The average daily high flow was 302 cfs on May 5th and October 10th. The average daily low flow was 239 cfs on June 30th.

The average daily discharge plots for Spring Creek, presented in Figure 32, may be used to identify several patterns that are reasonably consistent over the 27 years of record. First, the lowest average daily flow generally occurs in July with a range from June 30th to July 25th. Second, the highest average daily flow mostly occurs either in the spring (May or June) or in October (from 6th to 11th). Third, the July low flow is followed by an October high flow reflects a combination of the impacts of surface water irrigation and the impacts from cessation of ground-water pumping.

Relationship of Surface Water Irrigation and Ground-Water Discharge

Irrigation using both ground water and surface water occurs in the Near Blackfoot to Neeley reach of the Snake River. Figure 33, taken from Cosgrove and others (2006) shows irrigated ground from three sources: 1) ground water, 2) mixed ground water and surface water and 3) surface water.

The Aberdeen-Springfield Canal is the major supply source for surface-water irrigation on the northwest side of the Snake River in the Near-Blackfoot to Neeley reach. As such, the canal diversion records, presented in Figure 34, provide a general temporal view of this water supply source (diversion data obtained from B.A. Contor, 2007). Figure 34 shows an increase in annual diversion per water year from the 1930's into the early 1970's with a peak diversion of about 406,000 acre feet in the 1969 water year. A decrease in diversion rate occurred starting in the 1975 water year with most years less than 350,000 acre-feet per water year. Diversions during the 2000 water year were an exception to the decreasing trend with about 400,000 acre-feet diverted. The diversions during the 2001 through 2005 water years were all less than 300,000 acre feet.

The relationship between annual canal diversions and ground-water levels in a portion of the service area of the Aberdeen-Springfield Canal also is shown on Figure 34. The average annual (taken on a water-year basis) water-level elevations in well 5S 31E 27aba1 are shown along with canal diversions. Water-level data from this well have been presented three times previously in this report: 1) on Figure 17 to represent shallow ground water conditions north of the reservoir; 2) on Figure 27 to show Mundorff's (1967) relationship between calculated river gains and ground-water levels; and 3) on Figure 28 to show the relationship of ground-water levels to river gains calculated using the IDWR Reach Gain-Loss Program. Water-level data from well 5S 31E 27aba1 are presented in Figure 34 as an average over each water year (October 1 through the following September 30). The average values are based on a range in number of data points (weekly measurements in some years ranging to quarterly measurement after 1988). Figure 34 shows that average annual ground-water levels were in the range of 4,380 to 4,383 feet for the period of record up through 1988. With the exception of 1998, all of the average ground-water levels were lower than 4,380 feet. The lowest average ground-water level was 4,375 feet in 2004.

The ground-water levels in well 5S 31E 27aba1 do not immediately follow the decline in diversions in the canal that occurred starting in 1975. The general increase in diversions (with the exception of 1993) that occurred from 1984 to 2000 is also not directly replicated in the ground-water data. There are a number of possible reasons for the differences noted between canal diversion rates and shallow ground-water levels in a portion of the service area. These are: 1) changes in surface water application rates across the service area and in the general vicinity of the well; 2) changes in leakage rates from water delivery systems across the service area and in the general vicinity of the well; and 3) impacts from ground water pumping in the general vicinity of the well. Information is not available at the time of preparation of this report to develop a more detailed cause-effect relationship between canal diversions and ground-water levels in this single well. Sufficient data are available to say with certainty that changes in surface water irrigation practices in the general vicinity of the well 5S 31E 27aba1 have impacted shallow ground-water levels. It is likely that at least a portion of the water-level decline evident in the well hydrograph on Figure 34 is a result of ground-water pumping.

Relationship of Ground-Water Pumping and Ground-Water Discharge

Ground-water pumping from the Snake Plain aquifer is a major portion of the regional water budget. Figure 35, taken from Cosgrove and others (2006), shows that large areas are irrigated using ground water west and north of the Near Blackfoot to

Neeley reach. Other major ground-water pumping centers are located further west, southwest and northeast within the aquifer. The cumulative ground-water irrigation rights on the aquifer, as presented by Contor and others (2006) are presented in Figure 36. This plot shows a dramatic increase in ground-water irrigation rights starting in the 1950's and ending in the 1990's.

The seasonal hydrograph signature for a ground-water pumping area is a water-level high in the spring prior to the starting of pumping and a water-level low in the fall at the end of the pumping season. This is opposite to the signature of a surface-water irrigated area where ground-water levels are low in the spring prior to the start of irrigation and high in the fall at the end of the irrigation season.

None of the observation wells presented and discussed in the report section entitled *"Temporal Water-level Patterns in Wells"* has a seasonal ground-water pumping signature in the water-level record. The presence of the large tracts of land irrigated with surface water between the ground-water pumping areas and the Near Blackfoot to Neeley reach of the river appears to mask out any seasonal water-level changes from pumping wells. However, long-term water level trends such as those shown for wells 2N 31E 35dcc1 and 1S 30E 15bca1 on Figure 15 are detectable in deep wells in the area of interest. Examples are well 4S 33E 20cbb4 which is 738 feet deep (Figure 21) and well 3S 34E 22 dab2 which is 569 feet deep (Figure 23).

Ground-water pumping can impact ground-water discharge in the area northeast of the American Falls Reservoir via the following steps. First, there is a documented upward hydraulic gradient and thus upward ground-water flow from deep zones to shallow zones in the ground-water discharge area. An example of the upward hydraulic gradient is shown on Figure 21. Second, pumping impacts from throughout the aquifer are propagated through the aquifer to the discharge area. Deep wells near the discharge area have hydrographs similar to those near the center of the plain. Third, a decreased upward hydraulic gradient occurs because of greater water-level decline in the deeper zones than in the shallow zones. This is shown on Figure 21 by the comparison of the hydrographs for 4S 33E 20cbb1 at a depth of 62 feet to 20cbb4 at a depth of 738 feet. Fourth, the decreased upward hydraulic gradient results in a reduction in spring discharge.

The magnitude of upward ground-water flow from deep zones to shallow zones and then to discharge areas (such as springs) has not been directly estimated by any of the previous investigators. The magnitude of upward ground-water flow depends on the hydraulic gradient (for which some data are available) and the vertical hydraulic conductivity of the basalt and sediments in the area (for which essentially no data are available). The impacts of ground-water pumping on ground-water discharge also have not been estimated by any of the previous investigators except for model predictions presented in Cosgrove and others (2006).

MODEL REPRESENTATION OF THE HYDROGEOLOGIC SETTING

Characteristics of the ESPAM

ESPAM is a single layer, fixed transmissivity model with 104 rows and 209 columns constructed using the MODFLOW code (Cosgrove and others, 2006). All model cells are 1 mile x 1 mile with a 31.4 degree counter-clockwise rotation relative to east-west. Several types of boundaries were used in the model: 1) no flow, 2) specified flux and 3) head dependent.

The Snake River in the Near Blackfoot to Neeley reach is represented using the River Package. Cosgrove and others (2006) describe the function of river cells as follows.

> "Flow between the aquifer and river or drain cells is governed by equations which are based on Darcy's law (discharge is equal to the product of hydraulic conductivity times cross-sectional area times hydraulic gradient).. In a numerical model, for both river and drain cells, the hydraulic conductivity term represents the conductivity of the river-bed or drain sediments which controls the flow between the river/drain and the aquifer. The gradient … represents the head differential between river stage … and aquifer level" (pages 20-21).
>
> "The flow between the aquifer and a hydraulically connected surface water body is governed by (Darcy's Law)… In the MODFLOW River Package, (Darcy's Law) is implemented in terms of a) stage of the surface water body, b) aquifer water level and c) a conductance term describing the hydraulic conductivity of the riverbed … sediments and the wetted areas of the river bed. The user specifies river stage, elevation of the bottom of the river sediments and conductance of the riverbed sediments. As long as the water level in the aquifer is above the elevation of the bottom of the river sediments, the discharge to (or from) the river is calculated as (discharge is equal to the conductance multiplied by the difference of the river water-level elevation and the aquifer water-level elevation)… (page 30).
>
> "Since riverbed conductance is a lumped parameter (i.e. It represents multiple physical attributes) and impossible to measure, it is commonly estimated during model calibration" (page 32).

The area of the river and reservoir in the Near Blackfoot to Neeley reach is represented using river cells as is shown on Figure 37. Cosgrove and others (2006, Table 3) provide the following information for each of the river cells: 1) row and column (location in the model), 2) stage (for river or reservoir), 3) riverbed conductance in units of square feet per day and 4) riverbed elevation in feet. The stage information was given to represent field conditions. The riverbed elevation was in the range of about 39 to 53 feet lower than stage elevation. The riverbed conductance was held at 99,000 square feet per day for all of the river cells in the reach. As a comparison, the conductance term was set at 157,000 square feet per day for the cells in the Shelley to Near Blackfoot reach and 35,100 square feet per day for the cells in the Neeley to Minidoka reach.

The calibrated transmissivity values for the nodes in the portion of the model near the Near Blackfoot to Neeley reach were obtained from IDWR (Wylie, personal communication, 2008). Figure 38 shows transmissivity values for this portion of the

model in terms of ranges of values. The map shows that high transmissivity values (> 10,000,000 ft^2/day) are included in the model to represent aquifer characteristics north of the east end the American Falls Reservoir.

Calibration of the model was done using automated parameter estimation tools. Cosgrove and others (2006, page 90) describe the process as follows.

> "The goal of model calibration was to adjust model parameters (transmissivity, aquifer storage, riverbed conductance and drain conductance and elevation) until model-predicted values of aquifer water levels and discharges to the river matched observed values. The calibration was done in two steps. An initial steady state calibration was done to establish initial aquifer transmissivity and riverbed and drain conductance. After the initial steady state calibration, a coupled steady state and transient calibration was done. During the coupled steady state and transient calibration, the parameter estimation software would adjust aquifer storage and drain elevation during the transient portion, followed by a check of the steady state model fit. This forced the transient calibration to not only provide a 'best fit' to the transient data but to also honor the steady state observations. Changes to the transmissivity field and riverbed and drain conductance were allowed during the coupled steady state/transient calibration."

Cosgrove and others (2006) show comparisons of model predicted ground water levels as compared to field data. They also show model predicted river gains or losses in comparison to observed or calculated river gains or losses. Model output was compared to ground-water levels in selected wells and to calculated or measured reach gains or losses. The comparison of model predicted gain to calculated gain for the Near Blackfoot to Neeley reach is presented in Figure 39. The model predicted gains are a reasonable representation of the calculated gains over time, although with slightly less variability.

Model Representation of Site Hydrogeology

The Snake Plain aquifer model is of necessity a simplification of a complex ground-water flow system with complex interactions with surface water systems. The primary question is whether changes in the model are needed to make it better represent field conditions. Three topics are presented relative to representation of the Near Blackfoot to Neeley hydrogeology within the model.

- The general construction of the model in the vicinity of the Near Blackfoot to Neeley reach is appropriate for the intended uses of the model. However, construction of a single layer model with one-square mile node spacing does not allow assessment of vertical flow within the aquifer or discharge characteristics of individual springs or stream-gain areas.
- Representation of the Snake River including the American Falls Reservoir using the River Package is appropriate. Hydrogeologic conditions are such that higher riverbed conductance values should be applied to the area between the northeastern end of the reservoir and the Near Blackfoot gage than are applied for the body of the reservoir. The conductance value assigned for the reservoir should be low enough relative to the conductance value for the upper portion of the reach to limit direct discharge into the reservoir to a small value.

- The transmissivity array used in the model does not fit the general hydrogeologic setting of a basalt and gravel dominated system north and northeast of the American Falls Reservoir transitioning into a fine-grained, sedimentary-dominated system under the reservoir. Consideration should be given to making changes in model calibration to achieve a transmissivity array that better fits the hydrogeologic conceptual model. Care must be taken in that the transmissivity values of the single layer model need to represent not just the near-surface sediments and basalt but also the deeper basalt units.
- Consideration of multiple layers for the model should be taken carefully. A multiple layer model can provide an improved representation of areas such as upstream of the American Falls Reservoir where vertical hydraulic gradients are present. However, adding multiple layers increases complexity and thus increased uncertainty in model predictions. Also, data may not be currently available to support the construction and application of a multiple layer model.

CONCLUSIONS AND RECOMMENDATIONS

There is little doubt that ground water discharges to the Snake River in the Near Blackfoot to Neeley reach because the transmissivity in the general vicinity of the American Falls Reservoir is lower than in upstream areas. The gravel zone that hosts a shallow ground-water flow system along the Snake River essentially terminates against the fine-grained sediments of the American Falls Lake Beds and the Raft Formation. In the same way, basalt that makes up most of the Snake Plain aquifer occurs only as individual flows within a sequence of mostly fine-grained sediment. The lower transmissivity in the immediate vicinity of the American Falls Reservoir acts similar to a subsurface dam and results in ground-water levels in shallow and deep aquifers northeast of the reservoir at or above ground surface. The springs occur in these areas. There is a significant upward hydraulic gradient which indicates ground-water flows from deeper aquifers to shallow aquifers and then discharges as springs and stream gains.

The majority of ground-water discharge occurs upstream of the American Falls Reservoir, probably controlled dominantly by the subcrop of the Raft Formation. The amount of ground-water discharge directly into the bottom of the reservoir is unknown but believed to be small.

The ground water that discharges to the Snake River in the Near Blackfoot to Neeley reach is a combination of water from the shallow aquifer in gravel zones along the Snake River and upward flow from deeper aquifers that are hydraulically connected to the basalt system of the main Snake Plain aquifer. The percentage of the discharge that originates from the shallow gravel aquifer likely is higher than the percentage that originates from the deeper aquifer, but the relative amounts are unknown.

As with any ground-water system, temporal variations in the ground-water discharge in the Near Blackfoot to Neeley reach of the Snake River are related to water-level changes in the source aquifer. Higher discharge from the springs occurs because of higher ground-water levels. The converse is also true.

Changes in surface-water irrigation practices in recent years have decreased ground-water levels in shallow aquifers and thus have resulted in reduced ground-water

Exhibit 837 - Page 207

discharge in the Near Blackfoot to Neeley reach. Ground-water pumping has caused ground-water level declines in the main Snake Plain aquifer and is also a factor in reduced ground-water discharge in the Near Blackfoot to Neeley reach. The well hydrographs and the discharge hydrograph for Spring Creek represent a multiple overlay of impacts from changes in surface water irrigation practices combined with the impacts from ground-water pumping.

The Enhanced Snake Plain Aquifer Model (ESPAM) is a work in progress. Model construction and operation and then modification and improvement are part of a repetitive process that is tied to improved data collection and analysis. Specific recommendations with respect to the model include the following.

- Modify the transmissivity array in the Near Blackfoot to Neeley reach to better represent the subsurface hydrogeologic conditions. The changes should be made with the objective of forcing ground-water discharge from the model to occur primarily in the area between the American Falls Reservoir and Ferry Butte.
- Modify the ground-water conductance such that ground-water discharge occurs upstream from the northeast end of the reservoir and little discharge occurs directly to the American Falls Reservoir. The conductance can be modified to allow leakage from the southwestern end of the reservoir.
- To the extent possible, ground-water discharge to the Portneuf River should be represented in the model.

A revision to the existing water resource data collection network is needed in order to provide an improved basis for understanding the interaction of surface and ground-water systems in the Near Blackfoot to Neeley reach of the Snake River. Suggested improvements to the data collection network are noted below.

- Long-term discharge monitoring stations should be established on one or more additional spring/stream sites upstream from the American Falls Reservoir that have no direct impacts from irrigation return flows or diversions. Data analysis should include comparison to data from the Spring Creek station.
- Routine water-level measurement should be reinitiated on observations wells 4S 33E 25ddb and 4S 34E 8dbd. The measurement program should include either monthly measurements or preferably installation of data loggers.
- Additional collection of water-level data from shallow wells in the immediate vicinity of the Snake and Portneuf Rivers and near major springs is needed to develop a better understanding of ground-water levels and spring discharge and/or river gains.

1 Introduction

This report has been prepared on behalf of the Idaho Groundwater Appropriates Inc., ("IGWA") in connection with the *Fifth Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover* ("*Fifth Methodology Order*") and the *Final Order Regarding April 2023 Forecast Supply* ("*April 2023 As-Applied Order*") issued by the Director of the Idaho Department of Water Resources ("IDWR" or "Department") on April 21, 2023.

The *Fifth Methodology Order* defines the process and calculations utilized by the Director to predict material injury incurred by the Surface Water Coalition ("SWC"). The SWC comprises A&B Irrigation District ("A&B"), American Falls Reservoir District #2 ("AFRD2"), Burley Irrigation District ("BID"), Milner Irrigation District ("Milner"), Minidoka Irrigation District ("MID"), North Side Canal Company ("NSCC") and Twin Falls Canal Company ("TFCC"). The *April 2023 As-Applied Order* implements steps 1-3 of the Fifth Methodology Order to the conditions in existence at the beginning of the 2023 irrigation season.

The SWC entities divert surface waters of the Snake River at Minidoka Dam and Milner Dam. In 2005, the SWC filed a petition ("delivery call") with the Director seeking curtailment of junior-priority ground water rights that allegedly cause depletions of the Snake River and material injury to the SWC. The petition is governed by IDWR's Rules for Conjunctive Management of Surface and Ground Water Resources ("Conjunctive Management Rules) (IDAPA 37.03.11).

After an evidentiary hearing held in 2008, the hearing officer issued an *Opinion Constituting Findings of Fact, Conclusion of Law and Recommendations* on April 29, 2008 ("Hearing Officer Recommendation"). On September 5, 2008, the Director issued a final order in this matter ("2008 Final Order"), in which he ruled on all issues raised at the hearing with the exception of stating his methodology for determining material injury to the SWC reasonable in-season demand ("RISD") and reasonable carryover. On April 7, 2010, the Director issued the *Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover ("First Methodology Order")* setting forth the methodology for calculating material injury to RISD and reasonably carryover. A series of amendments to the First Methodology Order were made in subsequent years.

From 2016-2022, the Director administered water rights under the *Fourth Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover* ("*Fourth Methodology Order*"). On April 21st, 2023, the Director issued the *Fifth Methodology Order.* This expert report addresses changes made to the methodology in the *Fifth Methodology Order*, as well as the implementation of the new methodology in the *April 2023 As-Applied Order*, in preparation for a hearing currently scheduled for June 6-10th, 2023, concerning these orders.

In forming my opinions I have relied on review of the First Methodology Order and subsequent amendments thereto, my participation in the SWC Methodology Technical Working Group (TWG) meetings held by the Department in 2015 and 2022, my participation since 2012 as a member of the Eastern Snake Hydrologic Modeling Committee (ESHMC) which gives technical support to the Department on the development of the Eastern Snake Plain Aquifer Model (ESPAM), and my professional expertise as a hydrologist and groundwater modeler. I have examined maps and cross-sections of portions of the Eastern Snake Plain Aquifer (ESPA) and tabulations and diagrams of ESPA water rights, and I have drawn upon my accumulated knowledge of the water rights and hydrology of

the ESPA. To the extent that other information becomes available, the Director or the Department modifies any information presented, or new analysis and information becomes available, I reserve the right to modify or expand upon my opinions related to this case.

1.1 Report Organization

This report is organized into 5 sections, beginning with this introduction. Section 2 presents analysis and opinions related to the Fifth Methodology and the April 2023 As-Applied Order, including components of the RISD calculation involving irrigated acres, baseline year, and reasonable carryover. Section 3 discusses the simulation of curtailment of junior groundwater rights using the ESPAM model, including background and overview of the ESPAM model development, calibration, uncertainty, and recommendations for its application in the Fifth Methodology Order. Section 4 is a summary of my conclusions, and section 5 presents sources of information relied upon for my analysis.

2 Director's Methodology and As-Applied Order

2.1 Reasonable In-Season Demand (RISD)

2.1.1 Background

The First Methodology Order laid out the Director's methodology for determining material injury to SWC's Reasonable In-Season Demand (RISD) and Reasonable Carryover. The First Methodology Order provides a brief overview of the methodology for RISD starting with paragraph 11, explaining that material injury is the product of the SWC's predicted water supply and predicted water demand stating:

> In-season demand shortfalls will be computed by taking the difference between the RISD and forecast supply ("FS"). Initially RISD will be equal to the historic demands associated with a baseline year or years ("BLY") as selected by the Director, but will be corrected during the season to account for variations in climate and water supply between the BLY and actual conditions. The above description is represented by the following equation:
>
> In-Season Demand Shortfall = RISD – Forecast Supply (FS)

In April, at the start of the irrigation season, RISD is determined solely by the BLY. As the irrigation season progresses, weather and canal system operations are taken into account to make adjustments to RISD according to the following equation:

$$(1)\ RISD_{milestone_x} = \sum_{j=1}^{m}\left(\frac{CWN_j}{E_{p_j}}\right) + \sum_{j=m+1}^{7} BD_j$$

Where:

$RISD_{milestone_x}$ = reasonable in-season demand at specified evaluation milestones during the irrigation season,
CWN = crop water need for month, j
E_p = baseline project efficiency for month j,
BD = baseline demand for month j,
j= index variable , and
m= upper bound of summation, equal to the month calculation occurs, where April =1, May =2, … October -7

Crop Water Need ("CWN") is the project-wide volume of irrigation water required for crop growth as calculated by the following equation:

(2) $CWN = \sum_{i=1}^{n}(ET_i - W_e)A_i$

Where:

CWN= crop water need,
ET_i= consumptive use of specific crop type,
W_e= estimate effective rainfall,
A_i= total irrigated area of specific crop type,
I= index variable representing the different specific crop types grown within the irrigation entity, and
n=upper bound of summation equal to the total number of different specific crop types grown within the irrigation entity.

2.1.2 Irrigated Acres

2.1.2.1 Background on Irrigated Acres

For the purpose of water rights administration, the Hearing Officer stated in the Hearing Officer's Recommendation at page 53 states: "Non-irrigated acres should not be considered in determining the irrigation supply necessary for SWC members." This recommendation was adopted in the 2008 Final Order, and was sustained on appeal. Accordingly, the First Methodology Order, paragraph 25 states:

> Estimates of irrigated acres from the hearing show a trend of decreasing irrigated acreage. R. Vol. 28, 5205-15; R. Vol. 37 at 7100. According to the Hearing Officer, beneficial use cannot occur on acres that have been hardened or are otherwise not irrigated. R. Vol. 37 at 7100.

2.1.2.2 2015 TWG regarding Irrigated Acres

On January 30, 2015, the Director instructed Department staff to convene a committee to recommend specific technical changes to the *Second Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-season Demand and Reasonable Carryover ("*Second Methodology Order") issued June 23, 2010. The Director requested improvements to the following components of the methodology:

1) Revising natural flow forecast methods for Twin Falls Canal Company.
2) Identifying more accurate and current crop data to determine crop water need.
3) Improving the mid-season reasonable in-season demand forecast.

In response, Department employee Matt Anders gave a presentation on February 19, 2015, to outside consultants, referred to as the Technical Working Group ("TWG"), titled *Proposed Modification to Method for Determining Reasonable In-Season Demand for the Surface Water Coalition: Irrigated Acres for SWC Members*. Table 2-1 shows the actual irrigated acres of each SWC entity presented to the TWG. The TWG was also provided a spreadsheet titled "DS_RISD Calculator_2014" with data used to

calculate the DS and RISD which included a summary of irrigated acres utilized in Protocol Calculations as shown in Table 2-2.

The acreage figures shown for BID, MID, and TFCC reflect the evidence that Scott King with SPF Water Engineering[1] provided at the evidentiary hearing in 2008 which analyzed hardened acres. It was my understanding in 2015 that these would be the irrigated acres used in the Methodology Order. However, my recent review of the Department's RISD calculation spreadsheet indicates that these acres were only applied to calculations 2000-2014. Note that the Methodology was not adopted until 2010 but the Department's RISD calculation sheet includes a hindcast starting in 2000.

In the Department staff presentations to the 2015 TWG it was made clear that the Department had not adopted any type of process for reviewing the irrigated acre figures reported annually by the SWC. Consequently, there was no incentive for SWC entities to keep an accurate accounting of irrigated acres, and few SWC entities provide annual updates to their irrigated acreage figures; most simply report that there has been no change in irrigated acreage. To ensure that the Department does not include non-irrigated acres in its calculation of RISD, I submitted comments to the TWG in 2015 stating that irrigate acres should by verified using satellite and/or aerial imagery. A copy of my comments in 2015 is included as ATTACHMENT A.

Table 2-1. Summary of SWC irrigated acres 2015 TWG.

SWC Member	2005-2007 SPF	2012 Partial Decrees	2013 SWC Submitted Shapefiles	2013 RISD

NSCC	154,067	5/11/2006	Director's Report

*For A&B the "area of surface water irr" value (15,924 ac) includes 1,176 enlargement acres that were included in the Department's recommendation.

Among the documents produced by the Department in connection with the upcoming hearing concerning the Fifth Methodology Order is a document titled *"DRAFT_SWC_Mapping_Procedures_Revised_Nov2014_v2_matt"* which appears to have been created in preparation for the 2015 TWG. The stated purpose of the document is to map the irrigated land for each of the seven SWC entities and establish a procedure for reviewing irrigated lands data submitted by SWC entities and for utilizing irrigated lands data developed by IDWR if SWC members do not submit irrigated lands data. The document indicates that irrigated lands data developed by IDWR will be used if SWC members do not submit irrigated lands data. It further indicates that as of October 2014, the latest irrigated lands data is from 2010. The document identifies information that may be utilized to identify actual irrigated acreage including the Place of Use (POU) of water rights with surface water as a source, POU of water rights with groundwater as a source, and the most recent Crop Data Layer (CDL) developed by USDA NASS which is released January for the previous year.

Under "Background Information" the document notes that irrigated lands data is not submitted by SWC members on an annual basis. That the last data for BID, MID, and TFCC is from 2013, and it does not indicate whether the source is surface water, groundwater, or mixed source. The document notes that the irrigated acres can change slightly from year to year because of permissible POU but that these should be minor changes. It also recommends that supplemental groundwater use be addressed, identifying the GIS 2006 groundwater and mixed source data layer used in ESPAM as a potential source of such information.

Consistent with this document, the irrigated acreage information in Table 2-1 was presented to the 2015 TWG with the inference that it would be utilized in the RISD component of the methodology. The use of the CDL USDA NASS data for crop mix was also presented and recommended by Department staff for incorporation in the RISD calculation. Department staff ultimately determined there was insufficient time for the committee to evaluate supplemental groundwater use given the extremely compressed timeframe of the 2015 TWG.

2.1.2.3 2022 TWG regarding Irrigated Acres

In a status conference held August 5, 2022, the Director issued a directive to Department staff to convene a TWG to review and provide comments on potential technical changes to the Fourth Methodology Order. Department staff were again tasked with RISD refinements, and Department staff presented some of their analysis on the differences between the current RISD method for CWN employing USDA NASS CDL data compared to Near Real Time METRIC (Mapping EvapoTranspiration at high Resolution and Internalized Calibration).

On November 17, 2022, Department staff gave a presentation on Near Real Time METRIC which included, as slide 6, an outline of the current method for calculating CWN, including "Remove non-irrigated land from CDL using the IDWR Irrigated Lands Dataset." Near Real Time METRIC provides a high-resolution data set that documents irrigated acreage in "near real time," making accurate irrigated acreage data available from the previous irrigation season and potentially in the current season.

However, in a subsequent presentation given on December 1, 2022, titled *Proposed Modification to Method for Determining Reasonable In-Season Demand for the Surface Water Coalition: Use of the Near Real Time Metric*, the acreage information shown in Table 2-3 was presented.

Table 2-3. Summary of SWC irrigated acres 2022 TWG.

SWC Member	Shapefile Acres	If Removed Non-Irrigated Acres with 2011 Irrigated Lands Dataset (IDWR)	If Removed Non-Irrigated Acres with 2017 Irrigated Lands Dataset (IDWR)	NRT METRIC Processing Acres 2021 (IDWR)	Methodology Acres
A&B	21,976 (PPU, 2010)	21,585	21,634	21,625	15,924 (SRBA Partial Decree)
AFRD2	69,279 (PPU, 2010)	68,368	66,606	68,384	62,361 (SRBA Partial Decree)
Burley	46,035 (SWC, 2013)	44,113	44,168	44,139	46,035 (SWC, 2013)
Milner	14,844 (PPU, 2010)	13,239	13,202	13,233	13,335 (SRBA Partial Decree)
Minidoka	75,340 (SWC, 2022)	71,295	72,016	71,073	75,340 (SWC, 2022)
NSCC	224,463 (PPU, 2010)	220,935	218,498	220,937	154,067 (SRBA Partial Decree)
TFCC	194,732 (SWC, 2013)	179,486	180,956	179,456	194,732 (SWC, 2013)

It became clear from this presentation that since 2015 the Department has not utilized the most accurate irrigated acreage data to calculate RISD, but has instead utilized the lesser of either the decreed acreage or the acreage reported by SWC, without making any effort to insure that non-irrigated acres are not being accounted for in the IDWR's calculation of RISD. The Department's RISD calculation sheet show that the "Methodology Acres" from Table 2-3 are used in calculation of CWN 2015-2022.

Department staff could not explain why the more accurate and reliable acreage data was not being used in the methodology.

Every technical analysis of irrigated acres consistently shows that TFCC is irrigating approximately 15,000 acres less than the 194,732 acre figure that TFCC reports to IDWR as being irrigated. The expert report of SPF Water Engineering submitted in 2008, IDWR's irrigated lands data sets from 2011 and 2017, and Near Real Time METRIC data from 2021, consistently demonstrate actual irrigated acreage of approximately 180,000 acres. (The IDWR irrigated lands data sets and Near Real Time METRIC are discussed further below.) It is clear that the Department is not using the best science available to determine irrigated acres in the Fifth Methodology Order, relying instead on outdated acreage figures provided by the SWC entities.

2.1.2.4 IDWR's High Resolution Irrigated Lands Dataset

The IDWR has invested years of time and staff to produce a large archive of high-resolution irrigated lands data. IDWR's Irrigated Lands dataset is a three-class land-use classification including irrigated, semi-irrigated and non-irrigated areas. This data set was developed at the request of the ESHMC. It is used to calculate the ET and consumptive use components that make up one of the most important input parameters to the ESPAM. Irrigated lands acreage, as defined by the IDWR Irrigated Lands dataset, directly affects the volume of evapotranspiration (ET) in the ESPAM model. Similarly, irrigated acreage directly affects the volume of ET used to calculate RISD.

IDWR's Irrigated Lands data set utilizes satellite imagery, National Agricultural Imagery Program (NAIP) imagery, Digital Orth Photo Quadrangle (DOQQ) imagery, and other in-house, scanned aerial imagery for determining irrigation status. Attribute assignment for the irrigation status (irrigated, non-irrigated, and semi-irrigated) is determined using satellite imagery. Landsat and Sentinel Imagery provides the analyst the ability to monitor ground, moisture, and vegetation conditions over the entire growing season. Hand digitizing field boundaries using the satellite data and imagery produces a very accurate and precise depiction of irrigated acres.

In conjunction with the image data, IDWR analysts use Common Land Unit (CLU) polygons of individual fields that were digitized from the National Agricultural Inventory Program (NAIP) imagery by the Farm Services Administration (FSA). IDWR uses the unattributed CLU polygons because they are an existing, recent, highly-detailed, vector dataset the IDWR could attribute easily as irrigated or non-irrigated. These polygons were then hand edited when IDWR began working with the CLU data. IDWR then goes through a three-step classification (Figure 2-1) where step 1) used Landsat satellite data, 2) used a combination of Landsat and NAIP digital photography, and 3) used NAIP photography and CLU data.

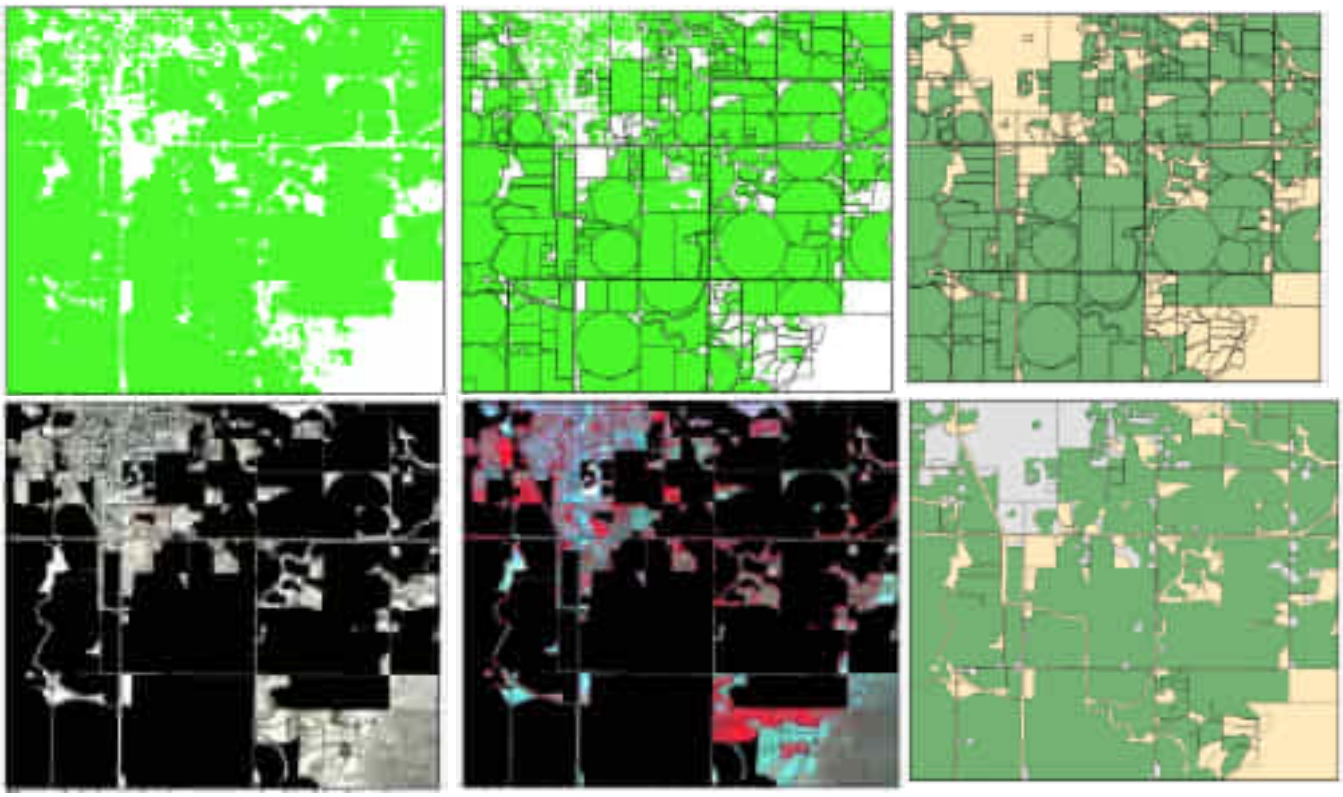

Figure 2-1: Sequence of IDWR Irrigated Land dataset processing from top left to bottom right 1)initial landsat-based classification out, 2) Landsat output with CLU polygons superimposed, 3) initial CLU polygon classification from irrigated (green) or non-irrigated based on 75% or greater rule, 4) irrigated polygons masked to black and superimposed on NAIP image, 5) irrigated polygons masked black and superimposed on Landsat data, 6) final edit classification with irrigated in green, non-irrigated in beige, and semi-irrigated (residential) in gray. (Source 2006 Irrigated Land Classification for the Eastern Snake Plain Aquifer Model, IDWR)

IDWR Irrigated Lands data sets for the ESPA include 1986, 1996, 2000, 2002, 2006, 2008, 2009, 2010, 2011, 2012, 2013, 2014, 2015, 2016, and 2017 (Wilkins, 2022). Department staff have reported that the Irrigated Lands data set 2021 could be complete by next year.

2.1.2.5 IDWR METRIC Dataset

IDWR and the University of Idaho worked under a NASA grant to develop the procedures to map ET from satellite data (Landsat) for water resources applications. The METRIC energy balance model was developed to compute and map ET using Landsat images. Dr. Rick Allen, Dr. M. Tasumi, and Dr. R. Trezza, of the University of Idaho, developed METRIC by making refinements to the Surface Energy Balance Algorithm for Land (SEBAL). Landsat measures visible, near-infrared, and thermal infrared radiation and has a pixel size small enough to map individual agricultural fields. METRIC also incorporates USBR AgirMet weather data into the modeling process. IDWR uses METRIC data (in years it is available) to calculate the ET rate for the ESPAM model (Figure 2-2). METRIC ET maps for eastern southern Idaho have been generated for 1986, 1996, 2000, 2006, 2008, 2009, 2010, 2011, 2013, 2016, 2017 and 2018. The partnership is also responsible for the NRT METRIC processing for 2019, 2020, and 2021.

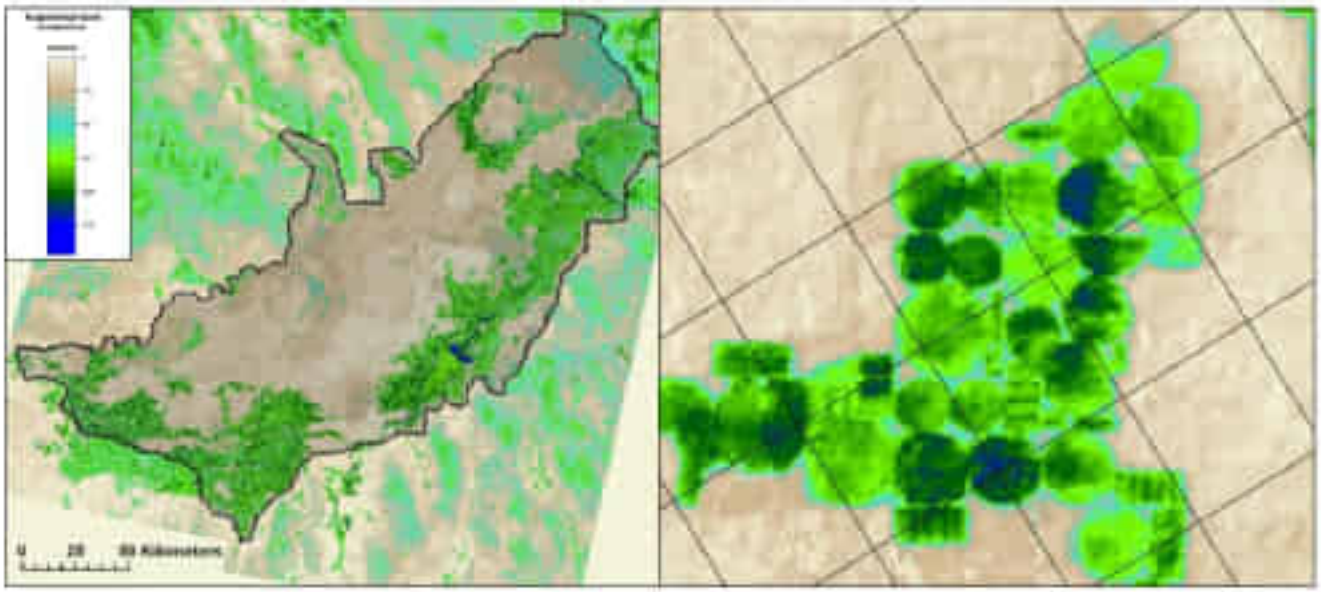

Figure 2-2: Example of seasonal 2002 METRIC ET within the ESPAM boundary (close up on the right). Each model grid cell is one square mile (Source IDWR Mapping Evapotranspiration; Hydrological Modeling https://idwr.idaho.gov/gis/mapping-evapotranspiration/).

2.1.2.6 Conclusions Regarding Irrigated Acres

The presentation by IDWR staff in November 2022 regarding NRT METRIC application revealed a significant shortcoming in the Fourth Methodology Order in that SWC irrigated acre datasets sometimes represent service areas as opposed to the actual irrigated land. If non-irrigated acres are to be excluded in calculating RISD, the Department should implement a review process in Step 1 of the Methodology Order that compares the irrigated acreage figures reported by SWC entities with the irrigated acreage data in the most recent Irrigated Lands data set and METRIC data. In any case, the Department should use the most accurate and reliable source of irrigated acreage data to calculate RISD in the Methodology Order.

As mentioned above, the most recent Irrigated Lands data set and the most recent METRIC data show that actual irrigated acreage within TFCC is approximately 15,000 acres less than the 194,732 acre figure that TFCC reports as irrigated. If the NRT METRIC acreage figure of 179,456 irrigated acres is utilized in the Department's RISD calculation sheet for 2022, the "Actual November Shortfall" calculated is reduced by 84,732 acre-feet (af). This underscores how critical it is that IDWR use care to identify actual irrigated acreage and calculate RISD based on actual irrigated acreage.

The Department's use of outdated irrigated acreage data highlights another problem of the Methodology Order relying on inferior data. The ESPAM is considered the best science available, and it utilizes the IDWR Irrigated Lands datasets and METRIC to calculate ET along with PRISM (Parameter-elevation Relationships on Independent Slopes Model) for precipitation. By contrast, in addition to using outdated irrigated acreage data, the Methodology Order uses an outdated approach with CDL data for crop mix, and Agrimet station data for the ET rate and precipitation. The ESPAM model also uses IDWR's determination for mixed sources lands where a groundwater fraction is applied on lands that have been designated as irrigated by both surface water and groundwater. The Fifth Methodology Order does not distinguish mixed source lands.

2.1.3 Baseline Year

In the First Methodology Order the BLY is characterized as a year or group of year(s) where water demands and water supplies can be used to as a benchmark to predict water demands in the current year at the start of the irrigation season. The RISD calculation allows for the BLY to adapt to actual conditions by adjustment up or down depending upon the actual water conditions for the irrigation season. The BLY selection criteria were based on three factors 1) climate, 2) available water supply, and 3) irrigation practices, to ensure the BLY is adequate to protect senior water users while providing some level of protection against unnecessary curtailment to the juniors.

BLY selection criteria concerning available water supply include above-average SWC diversions (Figure 2-3) and available SWC supply (Figure 2-4). BLY criteria concerning climate include above-average evapotranspiration (ET) (Figure 2-5) and Growing Degree Days (GDD) (Figure 2-6), both of which are a function of temperature, and below-average precipitation (Figure 2-7) to ensure the increased diversions in that year(s) were a function of crop water need (CWN) and not other factors. To capture current irrigation practices, identification of a BLY is limited to years subsequent to 1999. Id. at 7096.

These BLY selection criteria have been carried through from First Methodology Order to the Fifth Methodology Order; however, the BLY selected as the benchmark changed in the Third Methodology Order and the Fifth Methodology Order.

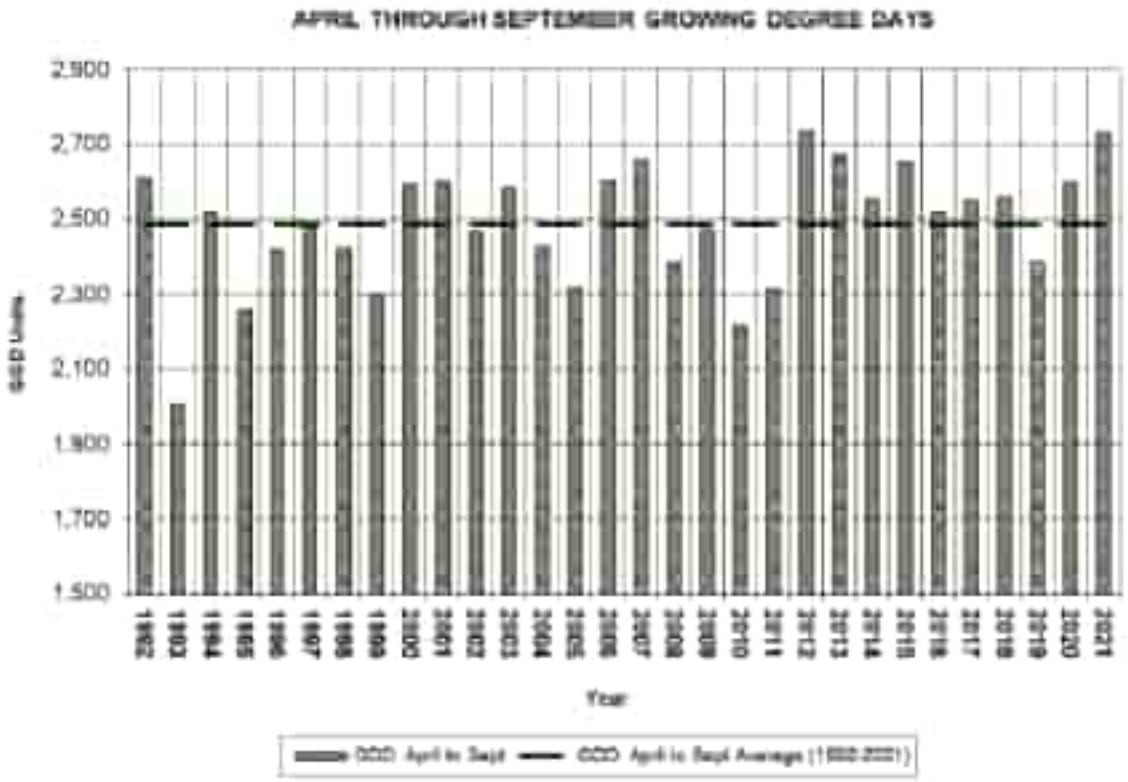

Figure 2-6. *Growing Degree Days ("GDD") for Twin Falls (Kimberly) AgriMet Site 1992-2021.*

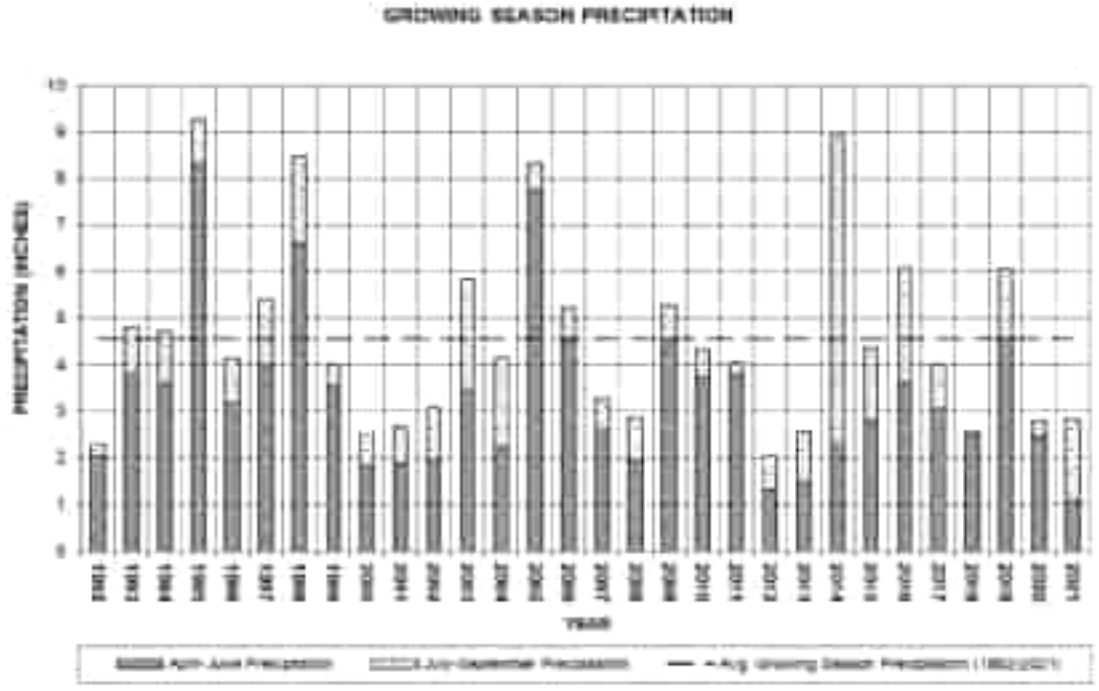

Figure 2-7. *Growing Season Precipitation at National Weather Service's Twin Falls Weather Station 1992– 2021.*

2.1.3.1 BLY First Methodology Order

In the First Methodology Order, paragraphs 27 and 28, found that "from the standpoint of total annual SWC diversion volumes, 2006 is an appropriate BLY with 97% of 2000-2008 total SWC diversion". The Director found that it would also be appropriate to use the values of 2006 and 2008 (06/08) to arrive at an average BLY that more strongly fits selection criteria for all members of the SWC. The First Methodology Order determined 06/08 as the appropriate average of years for the BLY selection. The 06/08 average is 100% of the average for 2000-2008 total SWC entity diversions. Both 2006 and the 06/08 average were determined to be appropriate BLYs.

They are appropriate because they are both so close to the BLY selection criteria averages, it is not necessary to make a determination with bias beyond that. The RISD calculation allows for the BLY to adapt to actual conditions by adjustment up or down depending upon the particular water conditions for the irrigation season. The average for the BLY criteria ensure the BLY is adequate to protect senior water users while providing some level of protection against unnecessary curtailment to the juniors.

2.1.3.2 BLY 2015 Third Amended Order Determination

In the 2015 Third Amended Final Oder the period of record for consideration of the BLY was extended to 2000-2014. It was found that the 06/08 average no longer met the criteria for the BLY.

The 2015 Third Amended Final Order determined 06/08/12 as the appropriate average of years for the BLY which is 101% of the average 2000-2014 total SWC entity diversions. The Director found that 2012 would also meet the criteria for the BLY which is 105% of the average 2000-2014 total SWC entity diversions. However, the Director found that because 2012 represents the maximum values for some of the BLY criteria during the period of analysis, 2012 is not an appropriate single-year BLY candidate.

In terms of total SWC diversions an 08/12 average for the BLY would have resulted in 104% of the average 2000-2014 SWC entity diversions. The 06/08/12 average (101% of average) appears to be preferred because it is nearer to the average BLY selection criteria for SWC diversions. Again indicating it is not necessary to make a determination with bias beyond that. The RISD calculation allows for the BLY to adapt to actual conditions by adjustment up or down depending upon the particular water conditions for the irrigation season. The average for the BLY criteria ensure the BLY is adequate to protect senior water users while providing some level of protection against unnecessary curtailment to the juniors.

2.1.3.3 BLY 2023 Fifth Methodology Order

In the 2023 Fifth Methodology Order the period of record for consideration of the BLY was extended to 2000-2021. The Department found that as individual years 2018 and 2020 satisfy all the BLY selection criteria. Additionally, the Department found that 2020 ranks as the second-highest year of total diversions for the SWC and is more than one standard deviation above the average for the years 2000-2021. The 2023 Fifth Methodology Order determined 2018 as the BLY which is 104% of the average 2000-2021 SWC entity diversions.

In terms of total SWC diversions the 06/18 average for the BLY would have resulted in 101% of the 2000-2021 average. Based on previous BLY determinations a selection closer to 100% should have been preferred. The difference between 1% and 4% of bias over the BLY selection criteria for total SWC diversions is 32,000 af and 128,000 af, respectively. For TFCC diversions 2018 as the BLY is 106% of average 2000-2021 where 6% bias is 60,000 af, this is almost the entire shortfall determination of 75,200 af determined in the Final Order Regarding April 2023 Forecast Supply. The 2010 and 2015 Orders make clear that this level of bias is not needed to define an appropriate BLY, 97-101% of the BLY selection criteria is adequate. The RISD calculation allows for the BLY to adapt to actual conditions by adjustment up or down depending upon the particular water conditions for the irrigation season. The average for the BLY criteria ensure the BLY is adequate to protect senior water users while providing some level of protection against unnecessary curtailment to the juniors.

A copy of my January, 2023 comments to the Department in response to their recommendations following the 2022 TWG is included as ATTACHMENT B. Some values in my comment letter were estimated from graphics provided to the TWG and have been corrected based on more accurate data below.

2.1.3.4 Conclusions on BLY selection in Methodology Order

IDWR should consider a percent of average for total SWC diversions and select an average of years closer to that of the 06/08 BLY (100%) and 06/08/12 BLY (101%) selected in 2010 and 2015, respectively. The average of diversion demands for the 2006 and 2018 (06/18) irrigation seasons meet all the BLY criteria (as shown in Table 2-4) and is 101% of total SWC diversion. The BLY of 06/18 has a better technical basis than 2018 as the BLY.

In a hindcast analysis by IDWR staff (ATTACHMENT C), the BLY 2018 causes a huge shift in the type of water year (i.e. wet, average, dry, very dry) where Demand Shortfalls are calculated. The hindcast showed a Demand Shortfall much more frequently in average and even wet years in addition to every dry or very dry year. When you compare the bell-shaped distribution of SWC total diversion demands for the POR 2000-2014 compared to 2000-2021 in Figure 2-8 and Figure 2-9, it is apparent that they are very similar. The average total SWC diversions for the period of record 2000-2014 and 2000-2021 are 3.15 maf and 3.20 maf, respectively. Similarly, the variability in the total SWC diversions for 2000-2014 and 2000-2021, as represented by the standard deviation, are also very close with values of 180,076 af and 178,587 af, respectively. The selection of BLY 2018 translates to a much higher level of bias and is not technically justified given the similarity between mean diversions and the standard deviation for the 2000-2021 POR versus the 2000-2014 POR.

An additional reason for targeting a specific percent of average in line with the average BLY criteria within the POR when establishing a BLY, and for using an average of years (or synthetic diversion volume), is that the process for selection of the BLY otherwise appears arbitrary and subjective. If IDWR staff are presented with multiple years within the POR that fit the criteria for a BLY, and there is no guidance or standard method for selecting a single BLY or average of years, the ultimate selection becomes purely subjective. Using an average of years (or even a synthetic diversion volume) that targets a prescribed percent of average is a more objective and technically defensible process.

Table 2-4. Baseline Year Alternatives and Baseline Year Criteria

BLY Criteria	Avg 2000-2021	BLY Avg 06/18	BLY 2018	BLY 2020
Above Avg SWC diversions	3.20 maf	3.21 maf	3.34 maf	3.54 maf
Above Avg GGD	2526 units	2579 units	2557 units	2597 units
Above Avg ET	1238 mm/d	1265 mm/d	1275 mm/d	1281 mm/d
Blw Avg Precip	4.27 in	3.88 in	2.54 in	2.79 in
Abv Avg SWC Supply	7.45 maf	8.56 maf	9.04 maf	8.22 maf

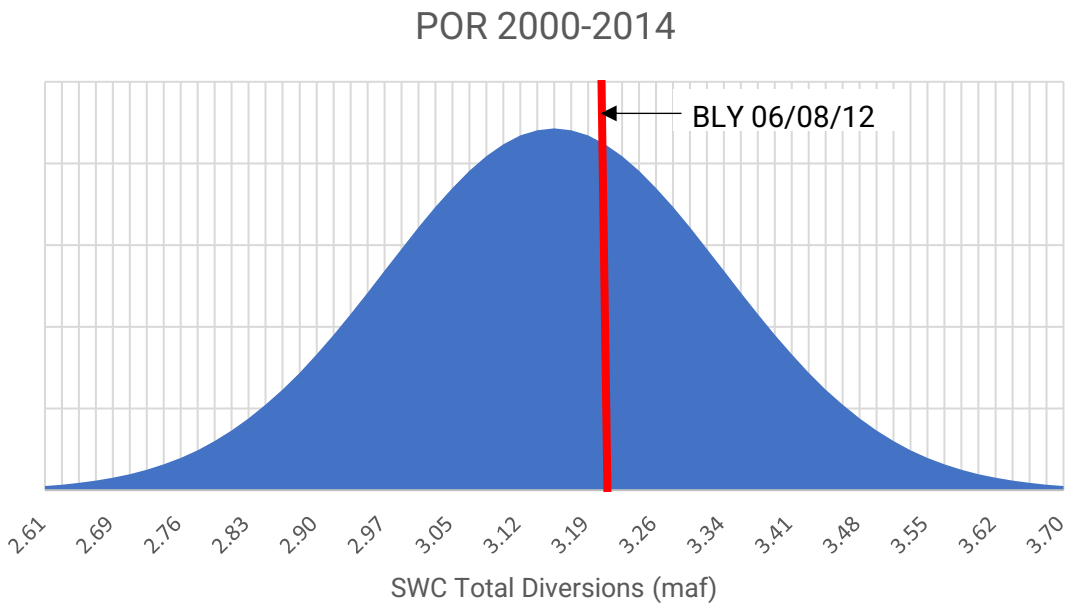

Figure 2-8: Bell Curve of SWC Total Diversion over the POR 2000-2014, the red line shows where the selected BLY 06/08/12 for the 4th Methodology Order falls within the normal distribution.

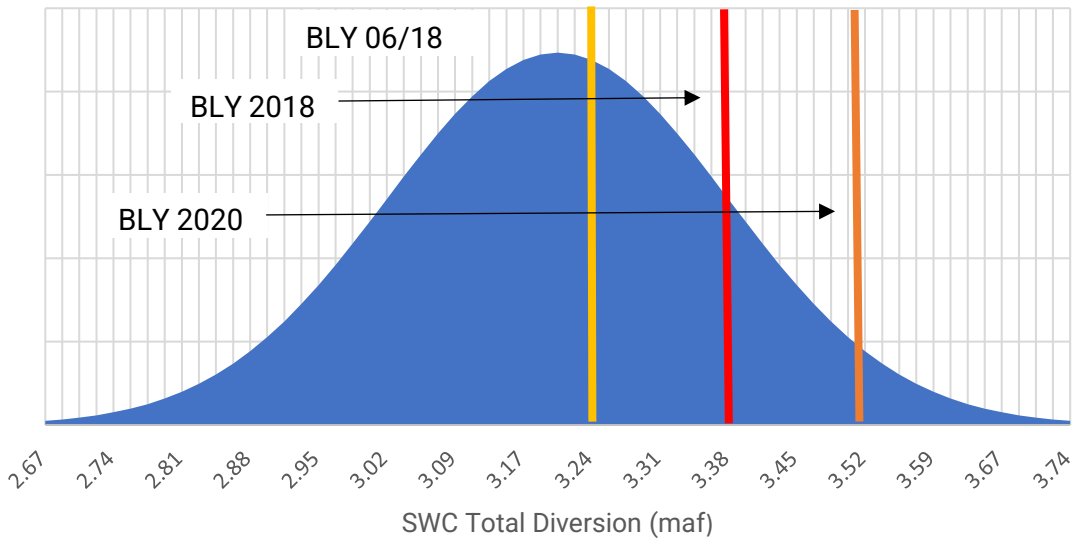

Figure 2-9: Bell Curve of SWC Total Diversion over the POR 2000-2021, the yellow line, red line, and orange line show where the proposed BLY 06/18, 2018 and 2020 falls within the normal distribution, respectively.

Another reason a better alternative would be to use diversion demands for the 06/18 irrigation seasons for the BLY is that there were unique hydrologic circumstances in 2018 that I don't believe represent the typical dry year. The 2017/2018 snowpack was very high and water year forecasts and early season streamflow led to positive water supply forecasts which resulted in a large amount of aquifer recharge in 2018. Department staff acknowledged the technical difficulties in sorting out surface water allocation adjustments like recharge in applying the Methodology Order. In the Department's RISD calculation sheet for "Demand" the table titled "SWC-Monthly Wheeled Water and In-Season Recharge Adjustment Factors (ac-ft)" show the adjustment for recharge and wheeled water. For 2018 there is a note about AFRD2 recharging between 5,000-10,000 af of recharge to MP31 for Magic Valley GWD and the calculation shows only 5,000 af of recharge was accounted for. Additionally IGWA's SWC Settlement Performance Report shows almost 4,000 af of recharge by North Snake GWD through NSCC that is not accounted. This creates a consistent bias of potentially 9,000 af in the application of 2018 as the BLY. This unaccounted for recharge water artificially inflates the 2018 BLY Demand and would directly artificially increase the DS amount calculated in April. The positive water supply outlook in 2018 may have also resulted in less stringent surface water administration and ultimately higher diversions than the crop water need alone would predict.

The BLY criteria concerning precipitation also reveal that 2018 is an extremely low precipitation year. Twin Falls Agrimet station data show the 2018 irrigation season is the only year in the 1992-2021 POR with a zero-precipitation total for July-September and that total irrigation precipitation for 2018 is about one standard deviation below the average. The fact that almost any individual water year will have some unique circumstance is a good reason for continuing to define the BLY based on an average of years as the Methodology Order has previously applied.

2.2 Forecast Supply (FS)

As previously described the shortfall issued in the Methodology Order is the difference between the forecast supply and the forecast demand for each SWC member. The forecast supply has two components: the predicted natural flow supply and the predicted storage allocation for each SWC member. The Department undertakes an April forecast and mid-irrigation season forecast.

2.2.1.1 2015 TWG regarding Forecast Supply

On January 30, 2015 the Director issued an order to staff directing them to convene a TWG to recommend specific changes to the Second Methodology Order. One of the specific recommendations for technical changes was revising the natural flow forecast for Twin Falls Canal Company.

Department staff presented analysis where both single linear regression and multiple linear regression models were considered over the period of record 1990-2013. New multiple linear regression models were recommended to replace existing regression models for TFCC, AFRD2, BID, MID, and NSCC.

In the April forecast for these entities, the final predictor variables selected included the total April through July natural flow in the Snake River near Heise and the total November to March discharge at Box Canyon Springs. Natural flow at Heise is considered a good April predictor of supplied by snowmelt, whereas Box Canyon Springs, was considered by Department staff to be a good indicator for the natural flow supplied by reach gains in the Blackfoot to Milner reach. I disagree with the latter as will be described in a later section.

For the July forecast new forecast models were developed for each SWC member. July natural flow predictors for A&B and AFRD2 are based on Snow Water Equivalent (SWE) Two Oceans Plateau Snotel on July 1. The regressions models for BID, MID, and NSCC include natural flow in Snake River near Heise (April-June), SWE Two Oceans Plateau Snotel on June 15, and March depth to water at well 05S31E27ABA1. I disagree with the use of well 05S31E27ABA1 as will be described in a later section. The predictors in the regression model for TFCC includes Snake River near Heise natural flow (April-June), SWE at Two Oceans Plateau Snotel on June 15, and Spring Creek discharge (January-May).

Table 2-5 shows a summary of all the variables tested in for the linear regression models presented to the TWG in 2015.

2.2.1.2 2022 TWG regarding Forecast Supply

In the 2022 TWG the Department presented December 14, 2022 a presentation on an evaluation of the April and July forecast supply models. This presentation was primarily an overview of how the forecast supply models performed 2014-2022 based on their R^2 values. Unlike the 2015 TWG improving the forecast supply models did not seem to be a priority in 2022 and only a very limited analysis concerning potential model improvement was performed. Table 2-6 shows the list of predictors tested in the 2022 TWG, where the only new predictors were two individual wells and the Sentinel Well index, none of which were found to improve the models for which they were tested.

Table 2-6. Variables Tested in 2022 Multiple Linear Regression Models

Variable Name	Description	Units
HeiseAprtoJulKAF	**USBR Hydromet Heise Natural Flow April-July**	**KAF**
Box11to3	**USGS 13095500 BOX CANYON SPRINGS NR WENDELL ID Total Flow November-March**	**AF**

	Sentinel Wells	feet
	WELL 05S31E27ABA1 (Mar 15)	feet
Variables in Bold were used in the models		

Department staff did not make a recommendation on updating April and July regression models to improve their predictive power for natural flow supply. However, the presentation to the TWG on natural flow forecasting models did show the TFCC model is degrading in the R^2 value and has decreased from 0.86 in 2014 to 0.72 in 2022. The degradation is significant in that the R^2 values is an expression of the

explanatory power of the forecast model. The technical information presented to the TWG indicates that a revised natural flow method for TFCC should be evaluated and a recommendation for an improved method should be made. There was not sufficient time during the 2022 TWG or prior to the June hearing to perform the necessary analysis as described in section 2.2.3.

2.2.2 Concerns with Current FS Predictor Variables

The next section 2.2.3 outlines my recommendations for how the natural flow models should be developed and could be improved. Aside from those recommendations I have additional concerns about two of the predictors used in the current regression models.

The first is that Box Canyon spring flows are not representative of groundwater discharge to the near Blackfoot to Minidoka reach. Box Canyon spring discharges to the Snake River along the Kimberly to King Hill reach of the Snake River. A comparison of reach gains between the near Blackfoot to Minidoka and Kimberly to King Hill reach show that spring discharge between the reaches varies in response to changes in precipitation and irrigation practices. The hydrogeologic controls on spring discharge between these reaches are also different. Aside from the fact that groundwater contributes to both spring reaches there is no logical reason that Box Canyon Springs should be representative of gains to the near Blackfoot to Minidoka reach gains.

The second concern is related to the use of well 05S31E27ABA1 as a predictor for reach gains. This is a shallow well located near the American Falls Reservoir and located in an area irrigated using surface water. The well shows a rapid response to surface water irrigation practices (Ralston, 2008). The relationship between canal diversions and observed water levels mean that this is not a good representation of groundwater conditions and more likely correlates with near Blackfoot to Minidoka gains as related to surface water supply.

2.2.3 Recommendations on Improving the Natural Flow Models used in the Methodology

The accuracy of predicting April and July natural flow available to SWC entities is dependent on reasonable predictor variables and maintaining high R^2 values over the period of record. The process for natural flow forecast model revision should be standardized in-terms of defining how frequently a thorough re-evaluation of the predictors and models is done (i.e. 3-yrs, 5-yrs, or if R^2 value drops below a threshold). This should include re-evaluating previously tested predictors over the new POR, as well as, casting a new net of total predictors for consideration by the TWG.

The standardized process should include a multicollinearity analysis to screen out variables selected to be predicted that are correlated with one another followed by something like a stepwise regression analysis used to select the most suitable model structure for predicting natural flow.

There was not time for Lynker to perform a proper analysis to demonstrate if there are more accurate models to consider in the natural flow predictions. If time had allowed Lynker would have performed something similar to the following process.

Data collection is the first step in the process. Natural flows are largely controlled by natural hydrologic processes often starting in the sub-alpine and alpine environments. Processes include snow accumulation, evapotranspiration, runoff generation, groundwater flows, and subsurface filling/spilling of subsurface storage. Many data sets exist to describe the hydroclimatic state of water supply and demand in areas that ultimately impact the generation of natural flow.

However, it is difficult to objectively select which predictor variables should be included in a linear regression model. If too few predictor variables are selected, there is a risk of not accounting for an unforeseen control on natural inflows. On the other hand, if too many predictor variables are selected, there is a risk of over-fitting the model, which degrades a model's predictive fidelity. To circumvent this challenge, I propose using stepwise linear regression analysis to construct parsimonious models for the specific SWC entities.

A stepwise linear regression analysis is a regression technique whereby explanatory variables are selected by an automatic procedure that culminates in a parsimonious model that includes only the most important explanatory variables. Provided a list of uncorrelated candidate predictor variables, stepwise linear regression analysis starts with a "maximal" model, which includes all candidate variables. The analysis iteratively removes variables whose omission results in the most statistically insignificant deterioration of the model performance. The Akaike Information Criterion (AIC) is used to objectively quantify the significance variable omission. The variable omission process stops when all predictor variables in the model are statistically significant. Stepwise linear regression analysis is a data-driven approach to construct predictive models and test the utility of additional natural flow predictor variables.

Lynker's technical memorandum included as addendum to IDWR staff recommendations in 2015 laid out an alternative forecast model approach that I continue to think should be further investigated. A better approach would use forecasted flow at Heise or some alternative model that forecasts the physical natural flow supply with subsequent allocation of that physical supply among the rights of the SWC. The technical basis for this suggestion is that water rights administration creates a non-continuous and non-normally distributed dependent variable in the regression analysis. This is likely the reason it is difficult to find a high performing regression model for TFCC.

2.3 Reasonable Carryover

Reasonable Carryover is defined as the difference between the BLY demand and projected typical dry year supply. Reasonable Carryover = BLY Demand – Projected Supply (based on a typical dry year)

The Heise natural flow for the years 2002 and 2004 are well below the long-term average (1992-2021) but not the lowest years on record as shown in Figure 2-4. The percent of average for these years rank very similarly when comparing the period of record for 1990-2014 to the period of record 1990-2022, at 75-79% and 74-78%, respectively. The Fifth Methodology Order like the First Methodology Order, the 3rd Methodology Order, the 4th Methodology Order adopted the average of these years to represent the typical dry year supply.

The Fifth Methodology Order adopts 2018 as the BLY for demand. Like in the DS calculation in April the selection of 2018 as the BLY greatly increases the prediction of carryover need for the SWC (Table 2-7). When Department staff presented the difference in the projected carryover need to the 2022 TWG there was no analysis presented to indicate whether or not this increase in carryover storage was needed based on existing conditions over the time the Methodology Order has been applied. There was not time prior to my writing of this Expert Report to analyze the need for the increased projection of reasonable carryover needs to the SWC.

Table 2-7. Maximum Projected Carryover Need Fourth Methodology Order Compared to the 5th Amended Order

SWC Member	Fourth Methodology Order Reasonable Carryover (af)	5th Amended Order Reasonable Carryover (af)
A&B	18,500	22,696
AFRD2	11,500	93,160
Burley	0	2,495
Milner	4,800	16,072
Minidoka	0	0
NSCC	65,500	113,277
TFCC	25,200	86,834

2.4 Compounding Bias

Each component of the RISD and Forecast Supply calculations in the Methodology Order has a built-in bias in favor of the SWC. These biases are meant to adequately protect senior water users while providing a level of protection against unnecessary curtailment to juniors. However, these biases have a compounding effect as they propagate through the methodology, resulting in excessive Demand Shortfall predictions that provide essentially no protection against unnecessary curtailment of juniors.

This is apparent from the Department's "Summary of Hindcast SWC Delivery Call Demand Shortfall Calculation 2000-2022" which shows that the Methodology no longer offers any protection against unnecessary curtailment to the juniors. To the contrary, the Fifth Methodology Order leads to the curtailment of every junior groundwater right on the ESPA in most years even though TFCC diversion records (the SWC entity most often short and demanding the largest demand short fall volumes) demonstrate that it is short of water only occasionally. This section will analyze how the compounding biases in the Fifth Methodology Order concerning irrigated acres, BLY, FS, and Reasonable Carryover result in Demand Shortfalls that are unreasonable given the actual water supply and demand conditions over the period of record 2000-2022.

2.4.1 BLY 2018 in April Demand Shortfall Determination

IDWR completed a hindcast analysis 2000-2022 for the April Demand Shortfall volume with 2018 as the BLY, the results of this analysis are shown in column 2 in Table 2-8. The Department provided ESPAM files for May 1 curtailment dates of junior pumping ranging from Oct 1900 to April 1994 that included acres and cfs curtailed. I have used these for column 2-4 in Table 2-8 to estimate the curtailment date most closely associated with the DS calculated in the Department's hindcast. Note that under a transient ESPAM simulation any DS over about 97,700 af results in complete curtailment to the October 1900 date. The analysis shows that for the 23 years in the hindcast 14 years would have resulted in a complete curtailment of all the junior groundwater acres across the ESPA within the area of common groundwater. This means that 60% of the time using 2018 as BLY results in an April DS that demands

complete curtailment of junior groundwater rights and over 940,000 acres curtailed. In contrast column 6 shows TFCC diversion rates in incher per year and only 4 years show that their diversion rates are below the full diversion amount of 5/8" per acre (*emphasized in Bold*). The IDWR hindcast shows only 4 years over the 23-year period where less than 300,000 acres of junior groundwater rights would be curtailed. This demonstrates how extremely conservative the application of 2018 as a BLY in the April DS determination is and that the Methodology no longer offers any protection against unnecessary curtailment to the juniors.

Table 2-8. IDWR Hindcast of April Demand Shortfall with BLY 2018 and Lynker Estimated Jr GW Curtailment based on Sukow May 1 Curtailment model files

Year	April BLY 2018 (AF)	Estimated Jr GW Curtailment Date	Estimated Jr GW Acres Curtailed	Estimated Jr cfs Curtailed	TFFC inches per acre

2.4.2 Erroneous Non-Irrigated Acres for TFCC included in RISD November Actual Demand Shortfall Calculation

As detailed in section 2.1.2 the Department reverted to using out-dated irrigated acres for TFCC in their calculation of CWN for RISD starting in 2011. Based on the most current and accurate irrigated acres from IDWR's irrigated dataset I recalculated CWN for the November actual DS and show the

difference in Table 2-9. For the TFCC acres in my analysis I used IDWR's 2011 irrigated lands dataset for years 2011-2016, IDWR's 2017 irrigated lands dataset for years 2017-2020, and IDWR's 2021 NRT METRIC acres for years 2021-2022. This shows that the erroneous use of non-irrigated acres for TFCC results in up to 84,732 af in demand shortfall.

Table 2-9. IDWR Hindcast of November Actual Demand Shortfall based on IDWR RISD with out-dated TFCC acres applied to CWN and Lynker's Corrected RISD with most current TFCC acres

Year	Nov Actual DS (AF)-IDWR Calculation outdated acres	Nov Actual DS (AF)-Lynker Calculation updated acres	Erroneous Shortfall Volume

2.4.3 Bias in April Forecast Supply Models

The forecast supply models predictions are used to predict in April Snake River natural flow volumes for diversion by each SWC entity. To protect the senior SWC water rights each prediction of natural flow is reduced by one standard deviation. Where DS=FS-RISD, this decrease to the FS directly amounts to an equivalent increase in the DS calculated. There was not time prior to my writing of the Expert Report but I would have evaluated this bias in Forecast Supply with respect to the IDWR Hindcast presented in the previous sections.

Table 2-10. April Reduction to Forecast Supply Models for Natural Flow available to SWC entities

SWC Member	April Reduction to FS Prediction (af)
A&B	19,828
AFRD2	32,595
Burley	15,579
Milner	3,221

SWC Member	April Reduction to FS Prediction (af)
Minidoka	17,968
NSCC	54,217
TFCC	47,368

2.4.4 Bias in 2018 BLY for Reasonable Carryover

There was not time prior to my writing of this Expert Report to analyze the need for the increased projection of reasonable carryover needs to the SWC with the use of 2018 as the BLY. However, based on a hindcast analysis presented to the 2022 TWG comparing the Fourth and the Fifth Methodology Orders for Reasonable carryover we can see, like with the April DS determination, the use of 2018 creates a huge difference in how often and the type of water years in which the SWC are determined to have a shortfall to their carryover needs. Figure 2-10 is IDWR's hindcast analysis showing annual carryover volumes for TFCC 1995-2022 under the Fourth Methodology Order (BLY 06/08/12) and the Fifth Methodology Order (BLY 2018). The highlighted carryover volumes indicate years where a shortfall to reasonable carryover would be determined. We can see that under the Fourth Methodology Order only 3 out of the 30 years would have resulted in a carryover shortfall and that these all occurred in very dry or dry years. Under the Fifth Methodology Order 19 out of the 30 years would have resulted in a carryover shortfall and that these occur even in average and above average years (Figure 2-1).

			4th Amended Methodology	5th Amended Methodology
Name (AF)	Year	Upper Natural Flow April - July (UAF)	TFCC (AF)	TFCC (AF)
	2021	1,960	23,917	23,917
	1994	2,185	38,686	38,686

Figure 2-10: IDWR hindcast analysis showing annual carryover volumes for TFCC 1995-2022 under the Fourth Methodology Order (BLY 06/08/12) and the 5th Amended Order (BLY 2018). The highlighted carryover volumes indicate years where a shortfall to reasonable carryover would be determined.

2.4.5 Other sources of Bias in the Methodology

There are a few other sources of bias in the Methodology that increase the Demand Shortfall determination. One is that it appears that not all of the recharge water in 2018 diverted through the SWC systems has been removed in the calculation of Demand for 2018. Potentially 9,000 af have not been accounted for and this directly increases the Demand Shortfall calculated every year with 2018 used as the BLY.

The Department does not account for supplemental groundwater use on mixed source lands which represents an additional supply to the SWC.

A critical problem is that the BLY selection criteria method will continue to create additional bias. Under the established BLY criteria, increases in diversion by SWC result in higher BLY demands. There is no examination of acreage or efficiency. It needs to be established that any increase in diversion by SWC entities is related to beneficial use on irrigated lands and not caused by decreases in project efficiencies or diversion of water to meet other needs like hydropower production. As mentioned in

section 2.2.3, and raised in both my 2015 and 2022 TWG comments a better approach would use forecasted flow at Heise or some alternative model that forecasts the physical natural flow supply with subsequent allocation of that physical supply among the rights of the SWC.

3 Simulation of Curtailment of Junior Groundwater Rights Using the ESPAM Model

3.1 Background

The Enhanced Snake Plain Aquifer Model version 2.2 (ESPAM2.2) is the current configuration used for IDWR modeling of the Eastern Snake Plain Aquifer (ESPA). The ESPAM was created with review and input from the Eastern Snake Hydrologic Modeling Committee (ESHMC).

A copy of *Hydrology, Water Right and Groundwater Modeling Evaluation of Rangen Delivery Call* (Brendecke, 2012) is included as Attachment D, section 4.1 provides a detailed description of background on the ESPAM and development.

From the outset of the ESPAM modeling effort, it was recognized that there would be a need for future enhancements to the model as new information and modeling approaches became available. ESPAM version 2.2 is the current version released in 2021. Discussion regarding the scope of future enhancements began shortly after the release with a preliminary release target date for the next model in 2026. With each model version release potential objectives to advance the model are made with ESHMC input, not all of which are accomplished because there is either insufficient time, insufficient data or are generally considered a low priority.

3.2 Model Structure

ESPAM is developed in MODFLOW, a groundwater modeling environment developed by the U.S. Geological Survey (McDonald and Harbaugh, 1988; 2000). A copy of *Hydrology, Water Right and Groundwater Modeling Evaluation of Rangen Delivery Call* (Brendecke, 2012) is included as Attachment D, section 4.2 provides a detailed description of the ESPAM model structure.

ESPAM2.2 was converted to MODFLOW-USG a code developed by the USGS (Panday, et al, 2013). While the MODFLOW-USG code supports a wide variety of structured and unstructured grid types and includes the ability to have multiples layers across the whole domain or in select areas of the model. ESPAM2.2 uses the same structured grid as ESPAM2.1. ESPAM2.2 is represented as a single layer with uniform thickness. In the ESPAM the aquifer is represented within a defined model boundary by individual model cells at a one-mile by one-mile uniform grid. The MODFLOW code solves the equations of flow between these cells to determine aquifer responses to changes in inputs or outputs. MODFLOW has the capability to represent anisotropy (where flow occurs in preferential directions), but this feature has not been used in any versions of the ESPAM.

Key differences between ESPAM2.2 and its predecessors include a longer study period (2008-2018), the adoption of METRIC data to estimate ET, structural changes including American Falls Reservoir area springs and spring fed river reaches and the addition of the Portneuf River. Additional work also included adding the Menan gage to separate the Heise to Shelley river reach, additional calibration targets for river reaches, finer spatial resolution for aquifer recharge from surface water irrigation

entities, calibration methods, and structural changes to drain boundaries of the Kimberly to King Hill reach. ESPAM2.2, like its predecessor ESPAM2.1 (released 2013) uses monthly stress periods.

3.3 Model Calibration Process

The typical development of a groundwater flow model involves creating a conceptual model and water budget for the system to be represented. These form the basis for the model structure and model inputs. After formulation of the model the next step in development is calibration. Calibration is a form of "history matching" wherein initial values of model parameters (such as transmissivity) are adjusted to achieve a better correspondence between historical targets (e.g., measured water levels and spring and river flows) and model-predictions.

A copy of *Hydrology, Water Right and Groundwater Modeling Evaluation of Rangen Delivery Call* (Brendecke, 2012) is included as Attachment D, section 4.4 provides a detailed description of the ESPAM model calibration process.

The software program used to calibrate all versions of the ESPAM has been the model-independent Parameter ESTimation program (PEST) developed by John Doherty (Watermark, 2005). While the calibration of models with large numbers of parameters (such as ESPAM2.2) allows consideration of more factors affecting aquifer conditions, it increases the risk that any given PEST solution (i.e., an "optimal" set of parameter values) is not unique (Watermark, 2005). This means that there may be many other combinations of parameter values could produce a similarly minimized value of overall model error. This non-uniqueness creates one dimension of overall model uncertainty, which is discussed in more detail in a later section.

The parameters that PEST was allowed to adjust in ESPAM2.2 included aquifer parameters such as transmissivity and specific yield. In addition, PEST was allowed to manipulate a number of terms in the aquifer water budget where precise values could not be known (like recharge on non-irrigated lands and tributary valley underflow).

3.4 Model Uncertainty

Any groundwater model is necessarily a simplification from the real world. The simplifying assumptions must be made to model complex natural systems. ESPAM2.2 inherently has limitations and uncertainty. As noted by IDWR in the 2021 ESPAM2.2 Model Calibration report, water budget parameters are adjusted during calibration simultaneously with the aquifer properties transmissivity and specific yield, resulting in a non-unique solution. The calibration results for these aquifer parameters are affected by assumptions regarding the uncertainty of water budget parameters. The ramifications of this are discussed in more detail in a later section.

The courts have recognized ESPAM as the best science available. Accepting that does mean that the inherent uncertainty in the model should be ignored in its application. As IDWR notes in their 2021 report of ESPAM2.2 model predicted uncertainty:

> Acknowledgement and a general understanding of the uncertainty associated with predictions made by the ESPAM2.2 is important to guide the use of the model as a tool for water management and administration.

3.4.1 Overview of Model Uncertainty

Model uncertainty has several dimensions, and these have been described in various submittals to the ESHMC (e.g., Brendecke, 2009a,b; 2012). Essentially, the principal dimensions of model uncertainty are those associated with model conceptualization, with model input and with model calibration. While all of these dimensions are important, conceptual uncertainty is fundamental. No amount of data improvement, re-sampling or recalibration can correct errors stemming from incorrect (or simply incomplete) model conceptualization (Bredehoeft, 2005).

A copy of *Hydrology, Water Right and Groundwater Modeling Evaluation of Rangen Delivery Call* (Brendecke, 2012) is included as Attachment D, section 4.6 provides a detailed description of ESPAM model uncertainty.

3.4.2 Examples of ESPAM2.2 Conceptual Model Limitations Leading to Uncertainty in near Blackfoot to Minidoka Reach Gain Prediction

The predictive uncertainty analysis of ESPAM2.2 carried out by the IDWR explores only a limited aspect of model uncertainty and does not quantify overall model uncertainty.

Fundamental to overall model uncertainty is the uncertainty associated with the conceptual model reflected in ESPAM2.2. The predictive uncertainty analysis relies on a single conceptual model and does not explore uncertainty that arises from improper conceptualization of local geology and hydrologic conditions that influence discharge to the near Blackfoot to Minidoka Reach.

The ESPAM2.2 configuration with a single layer model representation is not adequate to represent the hydrogeologic controls on groundwater discharge to the near Blackfoot to Minidoka Reach. Several hydrogeologic studies were summarized by Ralston Hydrologic Services (“Ralston”) in their report *Hydrogeologic Analysis of the Near Blackfoot to Neeley Reach of the Snake River* prepared for IDWR in 2008 (ATTACHMENT E). This report characterizes the hydrogeological conceptual model for the near Blackfoot to Neeley reach of the Snake River.

The Quaternary basalt near the center of the Snake River plain is generally considered to host a single unconfined aquifer where average hydraulic conductivity of the basalt is extremely high. The inter-fingering of Quaternary basalt flows with fine-grained sediments (i.e. Raft River Formation and American Falls Lake Beds) in the vicinity of the American Falls Reservoir results in an aquifer system composed of individual aquifers and confining units (aquitards). The presences of fine-grained sediments around American Falls Reservoir likely result in lower transmissivity compared to the aquifer to northwest where these materials are absent. Northeast of the reservoir a shallow gravel unit roughly parallel to the Snake River is present.

The presence of the fine-grained sediments (Raft River Formation and American Falls Lake Beds) likely act as restriction for southwestward ground-water flow in both the basalt and the gravel along the Snake River. This results in upward hydraulic gradients and groundwater discharge in the form of springs and river gains. The inter-fingering of the basalt and fine-grained sediments in the vicinity of the American Falls Reservoir and the distribution of the gravel deposits to the northeast is illustrated in Figure 3-1 and Figure 3-2.

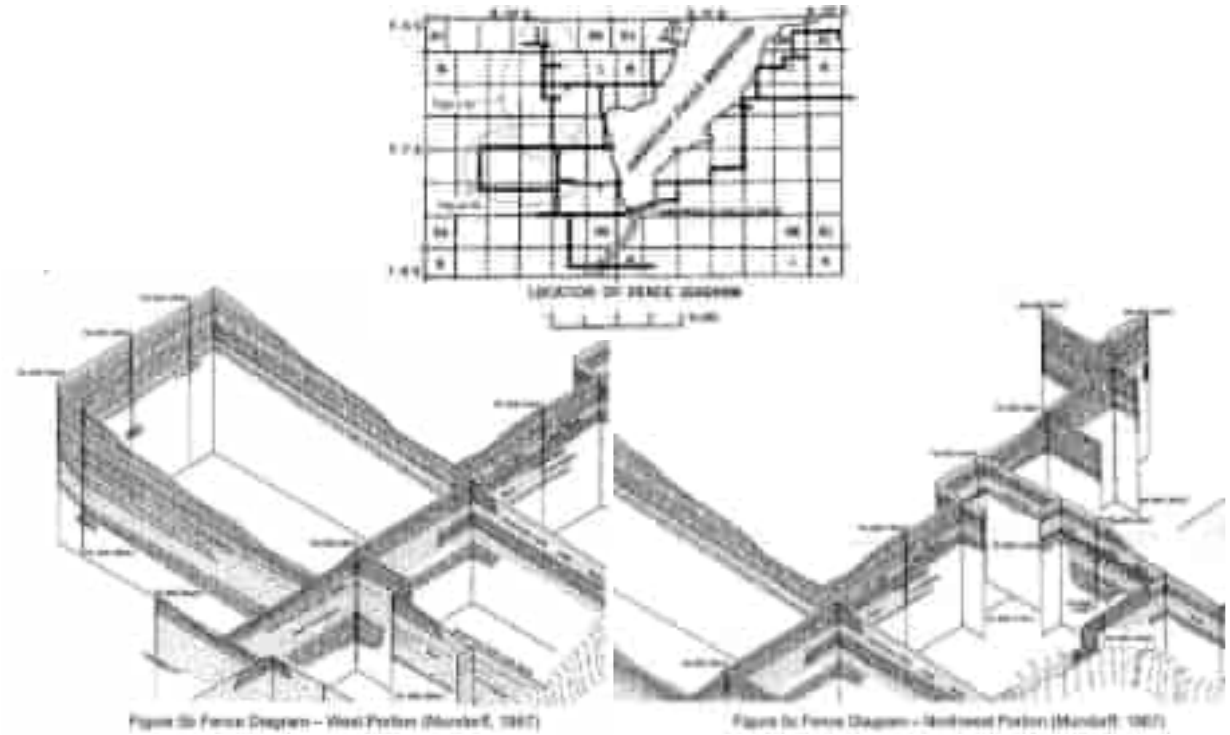

Figure 3-1: Excepts from Ralston (2008) Figures 5a,b,c showing Fence Diagrams of subsurface geology around the American Falls Reservoir from Mundorff (1967).

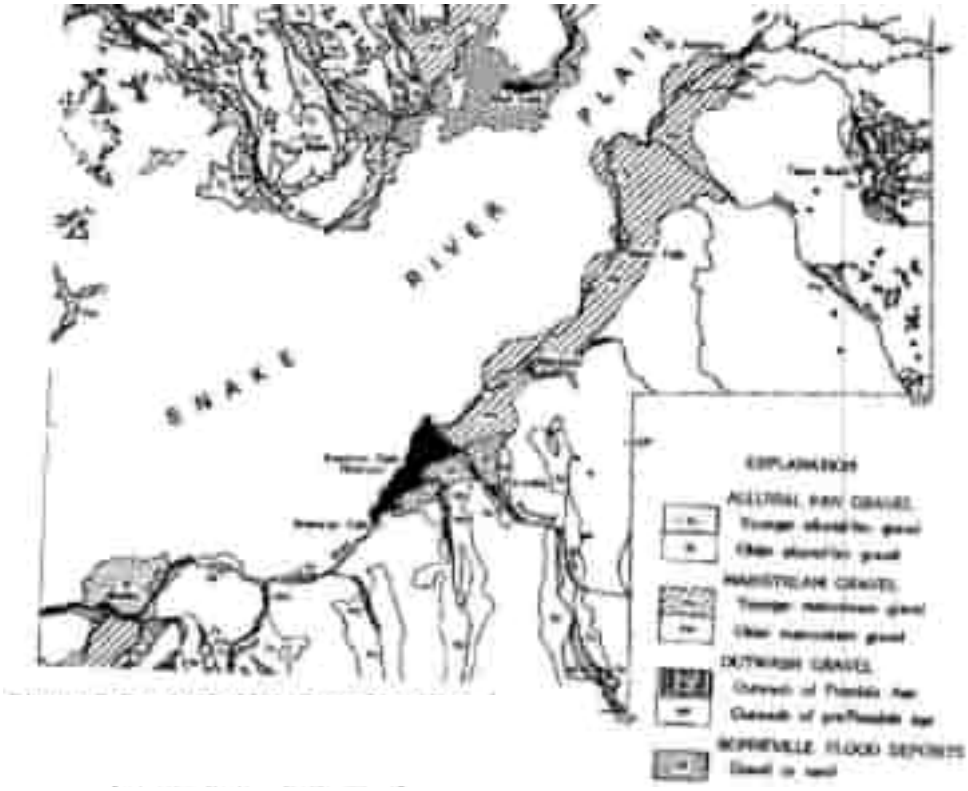

Figure 3-2: Except from Ralston (2008) Figure 8 of geologic map showing the gravel deposits along the Snake River by Piece and Scott, 1982).

These features mean that groundwater discharge to the near Blackfoot to Neeley reach is a function of the combination of water from shallow aquifers that are hydraulically connected to the basalt system of the main ESPA and vertical fluxes from the deeper aquifer units that are hydraulically connected. The magnitude of upward groundwater flow depends on the hydraulic gradient and the vertical hydraulic conductivity of the basalts and sediments in the areas. A single layer does not allow for the evaluation of vertical hydraulic conductivity or vertical flow within the aquifer or discharge characteristics of the individual springs or stream-gains areas.

The ESPAM2.2 transmissivity distribution (Figure 3-3) does not fit the know hydrogeologic characteristics of the region. Ralston (2008) describes how groundwater discharges to the Snake River in the near Blackfoot to Neeley reach because the transmissivity around and southwest of American Falls Reservoir is low compared to the upstream aquifer. The model should show high transmissivity representative of basalt and gravel dominated system north and northeast of American Falls Reservoir transitioning into low transmissivity representative fined-grained, sedimentary dominated system under the reservoir and to the southwest. Conceptual and calibration considerations should be made in the advancement of ESPAM2.2 to achieve a transmissivity array that better fits the hydrogeologic framework. In my recommendations for future improvements following the release of ESPAM2.2 I recommended an investigation to better understand groundwater gradients near the American Falls Reservoir reach.

3.4.3 Examples of ESPAM Input Parameters Leading to Uncertainty

As previously discussed, for ESPAM2.2 the water budget parameters like the ET rate for consumptive use by groundwater and components representing natural recharge to the groundwater system are adjusted during calibration simultaneously with the aquifer properties like transmissivity (T) and the aquifer storage specific yield (Sy), resulting in a non-unique solution. The calibration results for the aquifer parameters (T, Sy) are affected by assumptions regarding the uncertainty of water budget parameters.

ESPAM2.2 was adopted by the ESHMC following a vote in a September 9th, 2020 committee meeting. The Department had presented another version of the model for consideration to adopt as ESPAM2.2 in January 2020[2]. At the January, 2020 ESHMC meeting I presented an “impact analysis” of the proposed ESPAM2.2 version compared to ESPAM2.1 after my review of the model showed significant differences in model predictions, particularly for changes in water levels from simulated aquifer stresses. At the conclusion of the January ESHMC meeting it was decided that the validation run years (2015-2018) would be included in the ESPAM2.2 calibration, as well as, new irrigated lands maps (2015) to further evaluate the calibration results. At the September 2020 meeting IDWR again proposed a final ESPAM2.2 calibration with changes including updated water budget data through 2018.

3.4.3.1 ESPAM Aquifer Parameter Uncertainty ESPAM1.1 to ESPAM2.2

Figure 3-3 and Figure 3-4 below show the evolution of aquifer parameter distributions of transmissivity and specific yield, respectively, between ESPAM1.1, ESPAM2.1, ESPAM2.2 (proposed in January) and ESPAM2.2 (proposed in September and accepted as final).

[2]Based on calibration & modeling information provided to ESHMC September, 2019 and November, 2019

Compared to ESPAM2.1 the calibration results show a significant ESPA wide change of increased aquifer storage (Sy), as well as, generally lower aquifer transmissivity (T) that result in changes to pumping response functions and predicted stream depletion timing throughout the model domain.

Figure 3-5 shows the difference in simulated reach gains between ESPAM2.1 and ESPAM2.2 for the Departments 1/1/1961 curtailment scenario (Sukow, 2021). The ESPAM2.2 results in increased reach gains above Milner in response to curtailment. The near Blackfoot to Neeley reach shows one of the biggest increases overall with reach gains of 760 cfs and 931 cfs for curtailment of junior groundwater pumping to 1961priority date with ESPAM2.1 and ESPAM2.2, respectively. The percent difference is about 20%. The change in the steady state response function to the near Blackfoot to Minidoka reach between ESPAM2.1 and ESPAM2.2 is shown in Figure 3-6.

The Sentinel Wells which make-up the IGWA-SWC index for the 2015 Settlement Agreement were selected based on achieving the highest correlation (R^2~.63)[3] with the near Blackfoot to Minidoka reach gains. The aquifer level rise across the Sentinel Wells in ESPAM2.2 is about 50-60% of what was predicted with ESPAM2.1.

These changes between ESPAM2.1 and ESPAM2.2 illustrate the difference in predicted water level rise across the ESPA and modeled reach gains to the near Blackfoot to Minidoka from changes in aquifer properties transmissivity (T) and specific yield (Sy).

[3] Technique for Calculating Groundwater Level Index and Determining Compliance with Settlement Agreement Targets, August 8, 2016.

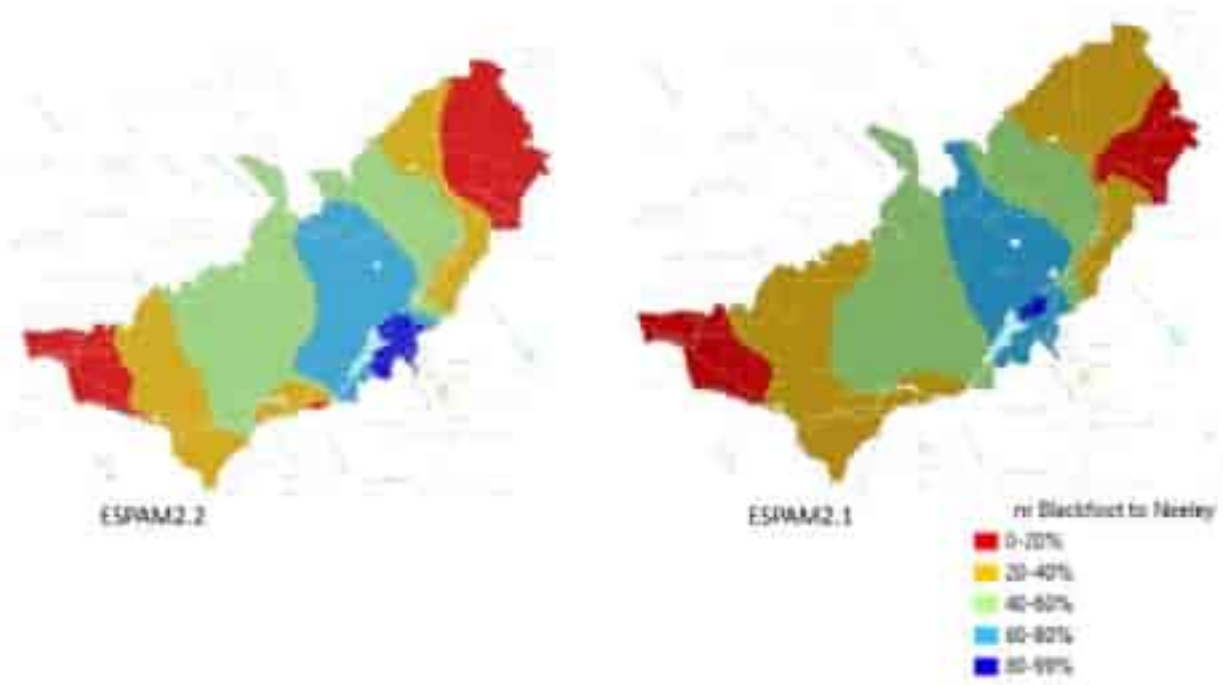

Figure 3-6: Changes in steady state response function for near Blackfoot to Minidoka river reach gains for ESPAM2.1(right) and ESPAM 2.2 (left).

3.4.3.2 ESPAM Water Budget Components Uncertainty ESPAM2.2

In ESPAM2.2 the aquifer parameters (T, Sy) and the water budget components (natural recharge, ET for consumptive groundwater use) are both adjusted during calibration. This means uncertainty in one of these components leads to uncertainty in the other. In the presentation of my impact analysis to ESHMC January, 2020 I was concerned about the change seen to aquifer storage following my review of the proposed ESPAM2.2 calibration, as shown in Figure 3-4. I did not believe the ESPA wide change in storage parameters could be explained by the localized structural model improvements and extending the period of record for the water budget components in ESPAM2.2. Because intermediary calibration results had not been presented to ESHMC it was impossible to parse out what change was leading to the new aquifer parameter distributions. I made the recommendation to the Department that ESPAM be calibrated with a step-wise approach so we could understand the result of each major model change, as well as, sensitivity testing for 1) changes in the calibration approach and 2) the METRIC processing method used to calculate ET for groundwater consumptive use

It was my belief that only either a change in the calibration method (e.g. pilot point distribution, regularization, or parameter weighting) or the METRIC processing for the ET rate for groundwater consumption (one of the biggest water budget components) could be responsible for such wide spread changes in the aquifer parameter values between ESPAM2.1 and ESPAM2.2.

My only concern around changes to the calibration method was that a simple change in calibration procedures should not significantly change the entire model results or if it did we should understand why.

I had two main areas of concern regarding the METRIC processing for ESPAM inputs. First, I was part of the METRIC TWG in 2015 that developed the processing methods for the METRIC data. The Department's processing of METRIC data for ESPAM included using a 90-meter buffer around the irrigated areas that ultimately increased the rate of ET used when applied to the irrigated lands acreage. There did not appear to be a well-founded reason around the specific choice of 90-m. That is why I recommended a sensitivity test to explore the impacts of this choice on the model calibration. The second, was that when I reviewed the calibration analysis for ESPAM2.2 it was obvious that the calibration tool PEST was adjusting parameters in ways that seemed to be compensating for the rate of groundwater ET being too high. For example, the significant increase in aquifer storage (Sy). Another example is the PEST adjustments to sources of natural recharge across the ESPA. The pre- and post-calibration time-series for water budget components that make up natural recharge are shown in Figure 3-7. It is evident that post-calibration results are much higher, indicating that to match model results to observed values the calibration tool PEST is trying to get more water into the ESPA. Again possibly compensating for groundwater ET rates being too high. This is particularly evident when comparing the pre- and post-calibration results for tributary underflow and recharge on non-irrigated lands.

Figure 3-7: Annual volume of net aquifer recharge, tributary underflow and recharge on non-irrigated lands water years 1981 through 2018

When the Department ultimately accepted the September 2020 ESPAM2.2 calibration as final they sent notice to the ESHMC members asking for suggestions for areas of improvement for the next version of ESPAM. Again, I recommended (along with several other issues), that a sensitivity analysis for the METRIC ET processing be performed. This was voted as a priority by the rest of the ESHMC. January 2023 the Department gave a presentation to ESHMC on METRIC where initial findings were that when the Department processing of METRIC for ESPAM was compared to both to a field-scale investigation using groundwater diversion data and two openly available sources of METRIC ET (ssebop and eemetric) the Department's method was consistently too high. The Department consulted with METRIC experts and concluded that it was not appropriate to apply a 90-m outer buffer and that best practices would apply an inward buffer to ensure that the most accurate METRIC pixel value was applied for to the irrigated lands dataset acres. These processing alternatives were presented to ESHMC May 2023 along with the Department's preliminary recalibration of ESPAM2.2 using the no buffer processing method alternative. Based on the preliminary recalibration of ESPAM (unbuffET_mile_003) the distribution for storage (Sy) and Transmissivity (T) compared to ESPAM2.2 are shown in Figure 3-8. This shows that model storage on average is less than ESPAM2.2, as well as, transmissivity with the alternative METRIC processing.

As previously discussed, the uncertainty in the water budget components directly results in the uncertainty of the aquifer parameters because errors in the water budget can be compensated by changes in aquifer properties to ensure the best model fit for observed versus simulated results like reach gains. The comparison of water budget components pre-and post-calibration based on the preliminary recalibration of ESPAM2.2 using alternative METRIC processing are shown in Figure 3-9.

There are several water budget components where the difference between the METRIC processing method is evident. Tributary basin under flow and recharge on non-irrigated lands are both about 300K af lower compared to ESPAM2.2 and we see that these components need to be adjusted much less pre- and post-calibration. Recharge on surface water irrigated lands is increased by about 300k af. The consumptive irrigation requirement (CIR) on groundwater irrigated lands is about 500K af lower. These differences demonstrate the uncertainty in the water budget components of the ESPAM model including those directly related to curtailment of junior groundwater rights. These uncertainties in the water budget inevitably result in uncertainty in the aquifer parameters that control the timing and magnitude of near Blackfoot to Minidoka reach gains in the ESPAM2.2 simulation of curtailment of junior groundwater rights.

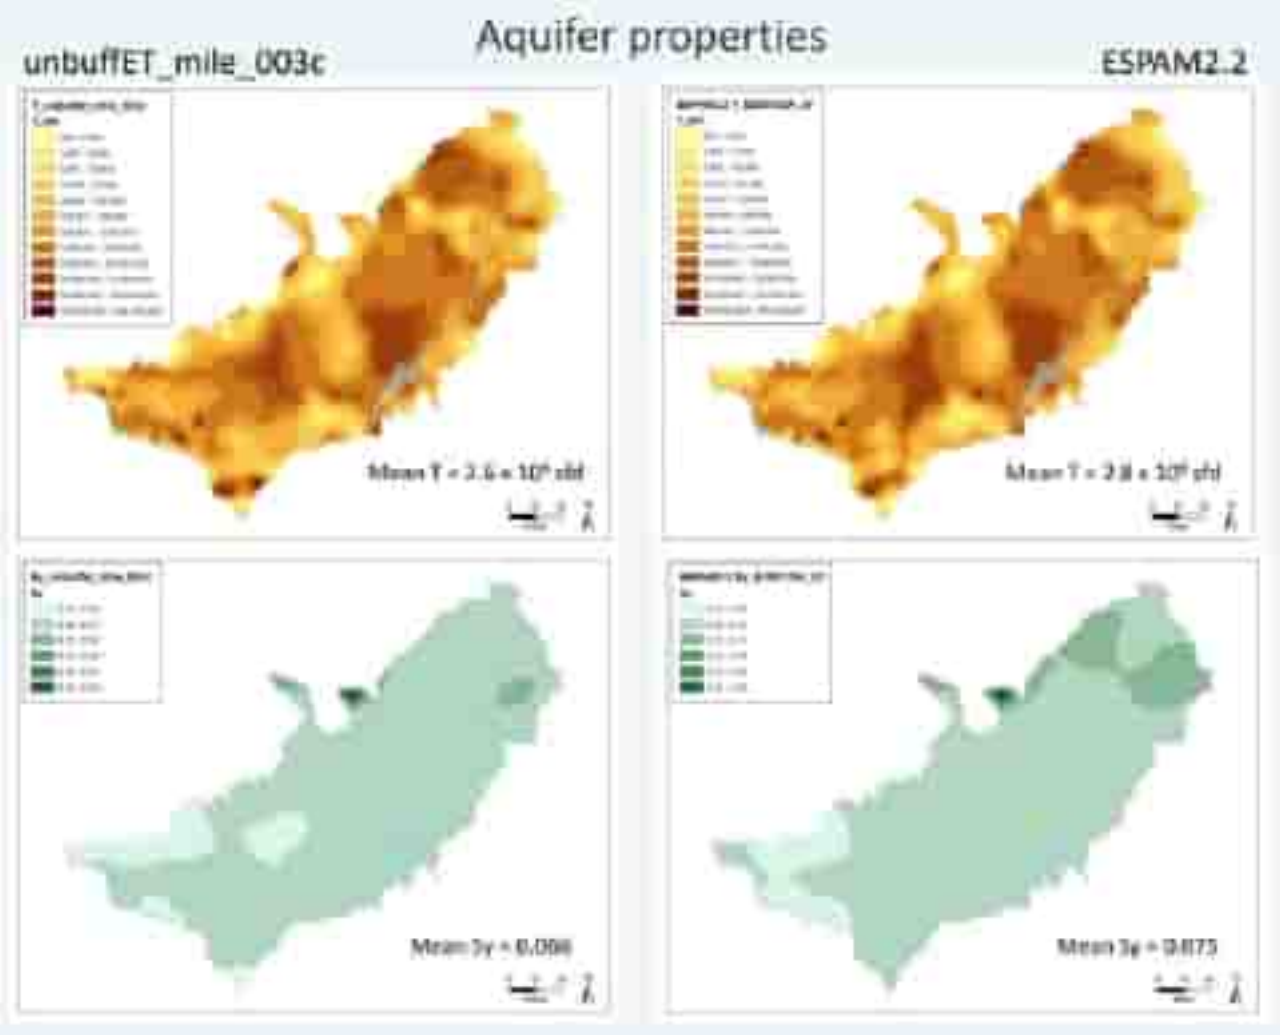

Figure 3-8: Comparison of Storage (Sy) and Transmissivity (T) distribution based on preliminary recalibration of ESPAM2.2 using alternative METRIC processing (model version "unbuffET_mile_003c"

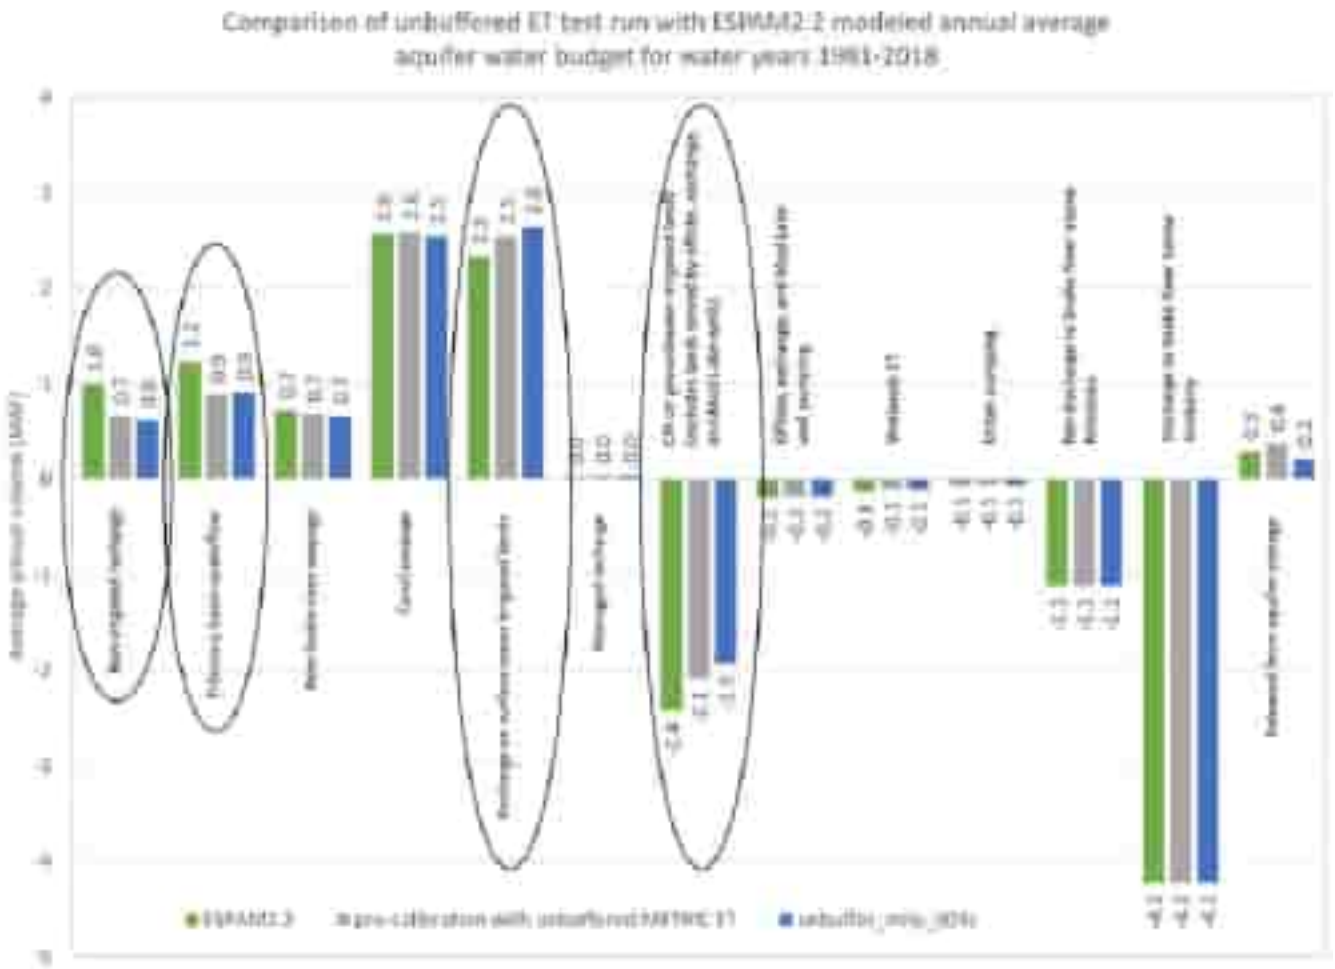

Figure 3-9: Comparison water budget components pre-and post-calibration based on preliminary recalibration of ESPAM2.2 using alternative METRIC processing (model version "unbuffET_mile_003c")

3.4.4 Conclusions on Model Uncertainty and the Application of ESPAM for Simulating Curtailment of Junior Groundwater Right for the Methodology

ESPAM2.2 is used in the Methodology to find the curtailment date of junior groundwater pumping that amounts to reach gains to the near Blackfoot to Minidoka reach of the Snake River equivalent to the Demand Shortfall calculated under the Methodology As-Applied Order. The Fifth Methodology Order transitions from a steady state to a transient ESPAM simulation to determine the amount of junior groundwater rights that must be curtailed for an in-season equivalent reach gain response to the Demand Shortfall. The April 2023 As-Applied Order determined a December 30, 1953 curtailment date and shows total proportionate share for all members of IGWA as 63,645 af.

IGWA requested that IDWR break the obligation down within IGWA by ground water district. As a response, IDWR provided the first two columns shown in Table 3-1. IGWA districts were interested in knowing the transient response given the curtailment scenario under the Fifth Methodology Order is now run using a transient ESPAM simulation. Jaxon Higgs provided the analysis but will be out of the country during the hearing and unable to testify. I reviewed the analysis and can testify to results

shown in Table 3-1. The IDWR MODFLOW wel input file was split by district based on their geographic boundaries as shown in Figure 3-10 and run with ESPAM2.2 to calculate individual district curtailment impact to the Near Blackfoot to Neeley reaches (SWC reaches) from May-September.

Table 3-1. Results of Jaxon Higgs Analysis on IGWA's Proportionate Share Related to Reach Gain Benefits and Acres Curtailed for the April 2023 As-Applied Order

1. Impact broken down by geographic boundary. Some non-members are included in each district. For example, the A&B usage is included in Magic Valley and North Snake GWDs. See accompanying map. Acre-ft rounded to 2 decimal places.
2. Total volume split geographically as described in note 1 from IDWR model input files from Jr12301953 run. Some slight conversion and rounding errors.
3. Acres provided by each district except Carey, Henry's Fork, and Madison. Based on breakdown of combined acres to provide effective acres per water right. 4
4. Baseline volume taken from 2022 Settlement Report submitted by IGWA to IDWR and the Surface Water Coalition. Represents average usage from 2010-2014.

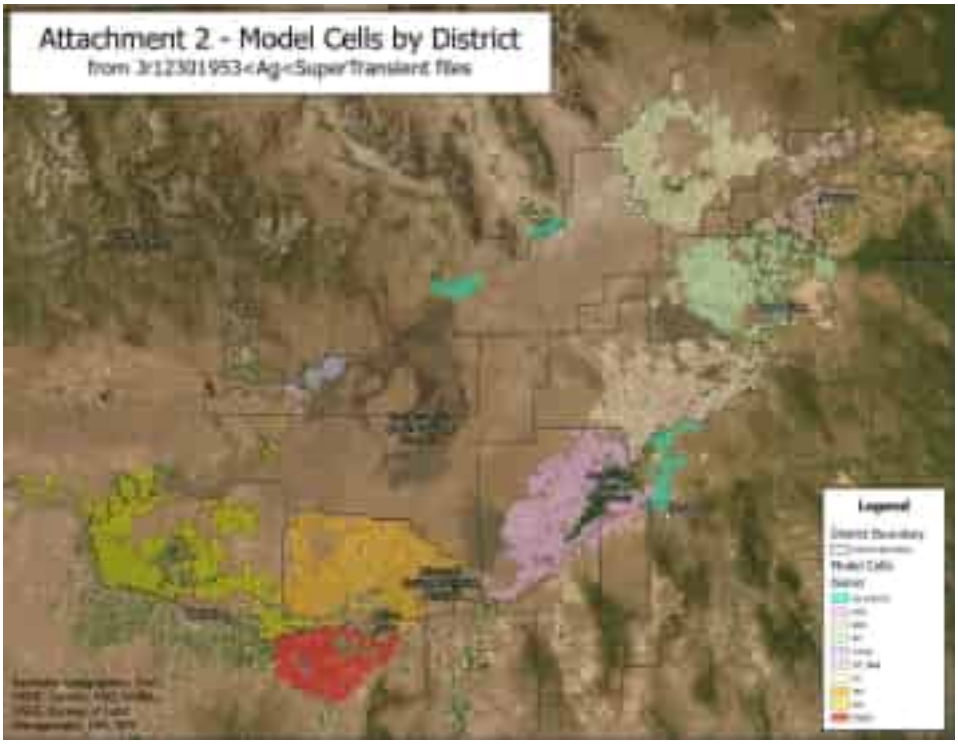

Figure 3-10: Distribution of junior groundwater pumping curtailed under 12/30/1953 priority date broken out by Groundwater District (Jaxon Higgs)

The results of Higgs' analysis show that the benefit to the SWC reach compared to the junior groundwater volume curtailed varies greatly by groundwater district. This is a result of their distance and hydrologic connection to the reach.

ESPAM2.2 is not sufficiently detailed in its representation of hydrogeologic conditions at the near Blackfoot to Minidoka reach to be used to accurately predict change in discharge due to curtailment of junior groundwater rights on the ESPA. Using ESPAM2.2 the number of junior groundwater acres that would be curtailed that do not have significant in-season benefits to the near Blackfoot to Minidoka reach is between 300,000-400,000 acres. The water from these rights will accrue to other connected river reaches, springs, without benefit to the SWC, or in years when the water is not needed. The wide-spread curtailment will, by any reasonable standard, result in waste of the resource.

ESPAM2.2 is highly simplified in the conceptual model in the near Blackfoot to Minidoka reach ignoring several critical hydrogeologic features that would make significant differences in predicted benefits of curtailment. The ESPAM water budget components related to junior groundwater use and the aquifer properties are uncertain and the variability in these components make significant differences in predicting benefits of curtailment. That ESPAM2.2 can fairly closely match observed discharge to the river is not proof that it represents the hydrogeological reality to sufficiently predict future behavior especially under aquifer wide water use conditions (e.g., curtailment of junior groundwater pumping).

If the Director uses ESPAM2.2 to quantify the benefits to the near Blackfoot to Minidoka reach from curtailment of junior groundwater uses, this quantification should reflect the substantial uncertainty in that model prediction and a trimline respective of the level of model uncertainty should be applied.

4 Summary of Conclusions

Irrigated Acreage

1. Evidence presented in prior hearings show a trend of decreasing irrigated acreage, particularly within TFCC due to urbanization of the City of Twin Falls and surrounding area. Beneficial use does not occur on acres that have been hardened or are otherwise not irrigated.
2. Every technical analysis of irrigated acres within TFCC consistently shows that TFCC is irrigating approximately 15,000 acres less than the 194,732 acre figure that TFCC reports to IDWR as being irrigated.
3. The Department is not using the best science available to determine irrigated acres in the Fifth Methodology Order, relying instead on outdated acreage figures provided by SWC entities.
4. The Department should implement a review process in Step 1 of the Methodology Order that compares the irrigated acreage figures reported by SWC entities with the irrigated acreage data in the most recent Irrigated Lands data set and/or using METRIC data. The Department should also account for supplemental groundwater use as a source of supply to SWC entities.

Baseline Year

5. The BLY demand for 2018 includes recharge water that has not been accounted for.
6. The BLY 2018 has total precipitation far below the average for the period of record.
7. Hindcast analysis show the BLY 2018 frequently predicts Demand Shortfalls for TFCC in years when TFCC is not actually short of water.

8. The BLY 2018 significantly increases the reasonable carryover demand shortfall in average and above average water supply years. No technical justification for this has been demonstrated.
9. In selecting the BLY, IDWR should consider a percent of average for SWC diversions within range of 97-101% and select an average of years closer to that of the BLY 06/08 (100%) and BLY 06/08/12 (101%) utilized in the First Methodology Order and Fourth Methodology Orders, respectively.
10. The average diversion demands for the 2006 and 2018 (06/18) irrigation seasons meet all the BLY criteria and is 101% of total SWC diversion. This 06/18 average (or a synthetic diversion volume) should be used as the BLY as it represents 101% of average total SWC diversion.
11. A critical problem is that the BLY selection criteria utilized to date create excessive bias in favor of senior water users. Under the current BLY criteria, increases in diversion by SWC result in higher BLY demands, incentivizing SWC entities to divert more water than is needed to grow crops, and disincentivizing water conveyance efficiency. A new BLY method should be developed that accounts for non-irrigated acres , ensures that any increase in diversion by SWC entities is related to beneficial use on irrigated lands and is not caused by decreases in project efficiencies or diversion of water to meet other needs like hydropower production, and incentivizes water conveyance efficiency.

Forecast Supply

12. The forecast supply model for TFCC is degrading in its explanatory power based on regression data, resulting in inaccurate predictions for natural flow to TFCC
13. Box Canyon Springs discharge is not representative of discharge to the near Blackfoot to Neeley Reach. This should not be used in the April Forecast Supply Models.
14. Well 05S31E27ABA1 is not representative of groundwater conditions in the vicinity of the near Blackfoot to Neeley Reach. This should not be used in the July Forecast Supply Models.
15. A better alternative to the FS models could use forecasted flow at Heise or other model that forecasts the physical natural flow supply with subsequent allocation of that physical supply among the rights of the SWC.

Model Uncertainty

16. ESPAM2.2 is, like all models, a simplified representation of reality, and its predictions contain a degree of uncertainty.
17. ESPAM is a single-layer model which assumes the ESPA is homogenous and isotropic. By contrast, the hydrogeology in the vicinity of the near Blackfoot to Minidoka reach suggests the aquifer system is multi-layered with vertical gradients that result in discharge to the reach that require a multi-layered modeled with anisotropic properties. ESPAM's current inability to represent multiple hydrogeologic layers may result in substantial misrepresentation of flow conditions in some parts of the aquifer.
18. Fundamental to overall model uncertainty is the uncertainty associated with the conceptual model reflected in ESPAM2.2. The predictive uncertainty analysis relies on a single conceptual model and does not explore the uncertainty that arises from improper conceptualization of local geologic and hydraulic conditions of the near Blackfoot to Minidoka reach.
19. The large number of parameters adjusted during calibration of ESPAM2.2 increases the likelihood that the model is not unique.

20. ESPAM2.2 has demonstrable uncertainty in the aquifer parameters for transmissivity and specific yield which will impact the timing and magnitude of reach gains to the near Blackfoot to Minidoka reach simulated under the curtailment of junior groundwater rights.
21. ESPAM2.2 has demonstrable uncertainty in the water budget components, particularly consumptive use of groundwater, which impact the timing and magnitude of reach gains to the near Blackfoot to Minidoka reach simulated under the curtailment of junior groundwater rights.
22. The predictive uncertainty analysis of ESPAM2.2 carried out by IDWR explores only a limited aspect of model uncertainty and does not quantify overall model uncertainty.
23. That ESPAM2.2 can fairly closely mimic the observed past behavior of the near Blackfoot to Minidoka reach is not proof that it accurately predicts the effect of curtailment of junior groundwater pumping.
24. ESPAM2.2 is not sufficiently detailed in either its general formulation or its representation of hydrogeologic conditions in the vicinity of the near Blackfoot to Minidoka reach to be used reliably to predict changes in reach gains due to curtailment of junior groundwater rights on the ESPA.
25. ESPAM2.2 represents the surrounding geology to the near Blackfoot to Minidoka reach in highly simplified form, omitting several key features and that would make significant differences in predicted benefits of curtailment.

Transient Application of ESPAM

26. Under a transient simulation with ESPAM2.2, the benefit to the near Blackfoot to Minidoka reach in-season compared to the junior groundwater volume curtailed varies greatly by groundwater district. This is a result of their distance and hydrologic connection to the reach.
27. Using ESPAM2.2 the number of junior groundwater acres that would be curtailed that do not have significant in-season benefits to the near Blackfoot to Minidoka reach is between 300,000-400,000 acres. The water from these rights will accrue to other connected river reaches, springs, without benefit to the SWC, or in years when the water is not needed. The wide-spread curtailment will, by any reasonable standard, result in waste of the resource.

MEMORANDUM

To: Gary Spackman, Director

From: Liz Cresto, Technical Hydrologist LC
Matt Anders, Technical Hydrologist MA

Date: March 16, 2015

Subject: Recommended revisions to the Surface Water Coalition Methodology

---

Introduction

On January 30, 2015, the Director of the Idaho Department of Water Resources (IDWR, Department) issued an order to staff directing them to convene a committee of experts to recommend specific technical changes to the "Second Amended Final Order Regarding Methodology For Determining Material Injury To Reasonable In-Season Demand And Reasonable Carryover" (Methodology) signed on June 23, 2010. Department staff created a committee in response to the Director's order composed of IDWR staff and experts representing parties involved in litigation of the Surface Water Coalition's (SWC) 2005 delivery call. In his January 30 order, the Director requested recommendations for technical changes to the Methodology by March 16, 2015, regarding the following specific issues:

1. Revising natural flow forecast methods for Twin Falls Canal Company.
2. Identifying more accurate and current crop data to determine crop water need.
3. Improving the mid-season reasonable in-season demand forecast.

Committee

The committee held multiple meetings and corresponded though email regarding the issues identified in the order. The committee comprises the following members:

Committee Member	Organization	Representing
Charles G. Brockway	Brockway Engineering	Surface Water Coalition
Chuck Brendecke	Lynker Technologies	Idaho Ground Water Users
Dave Shaw	ERO Resources	Surface Water Coalition
David Hoekema	IDWR	IDWR
Greg Sullivan	Spronk Water Engineers	City of Pocatello
Liz Cresto	IDWR	IDWR
Matt Anders	IDWR	IDWR
Scott King	SPF Water Engineering	Idaho Ground Water Users
Sean Vincent	IDWR	IDWR
Sophia Sigstedt	Lynker Technologies	Idaho Ground Water Users

The committee collectively decided that the most efficient method for consolidating member comments while still adhering to the March 16, 2015 deadline was to have committee members attach their comments to this memorandum. All of the committee members had an opportunity to review this memorandum and all of their comments that we received are attached in Appendix B.

Section 1 – Natural Flow Forecast

Background

The Methodology requires the Director to issue an order determining the demand shortfall of the SWC members for the irrigation season. The SWC members include A & B Irrigation District (A&B), American Falls Irrigation District #2 (AFRD2), Burley Irrigation District (BID), Milner Irrigation District (Milner), Minidoka Irrigation District (MID), North Side Canal Company (NSCC), and Twin Falls Canal Company (TFCC). The shortfall is the difference between the forecast supply and the forecast demand for each SWC member. The forecast supply is comprised of two components: the predicted natural flow supply and the predicted storage allocation for each SWC member. Pursuant to the Methodology, the Department undertakes an April forecast and mid-irrigation season forecast.

In the current Methodology, the April predicted natural flow supply is based on a regression analysis comparing the total natural flow in the Snake River near Heise between April and July to the annual natural flow diverted by each SWC member. While the Director only requested revisions to the natural flow forecast recommendations for TFCC, the committee also identified improved models for AFRD2, BID, MID, and NSCC through its work on revised natural flow forecast methods for TFCC. This memo includes recommendations for revising the April predicted natural flow supply forecasts for TFCC, AFRD2, BID, MID and NSCC.

The mid-irrigation season forecast is addressed in Step 6 of the Methodology. The forecast supply in Step 6 is the sum of the actual year-to-date natural flow diverted, plus the predicted natural flow supply for the remainder of the season, plus the actual preliminary storage allocation. The predicted natural flow supply for the remainder of the season was forecast by selecting an analogous year based on the Snake River Blackfoot to Milner reach gains. The selection of the analogous year typically occurred in August and a revised forecasted supply was issued. In working to meet the request of the Director's January 30 order, the committee reviewed a host of models that predict the natural flow supply for each SWC member from July 1 through October 31.

The natural flow supplies for each SWC member are comprised of natural flow in the Snake River passing the near Blackfoot gage and gains which occur in the Snake River between the Blackfoot to Milner reach. The committee reviewed several different models for predicting both the April and mid-season natural flow supply for each SWC member. While many different predictor variables were considered, the following variables were ultimately selected: natural flow in the Snake River near Heise as reported by the U.S. Bureau of Reclamation; snow water equivalent (SWE) data at the Two Oceans Plateau SNOTEL site; Box Canyon Springs discharge; Spring Creek discharge; and groundwater levels near American Falls Reservoir. The recommended model predictors vary by SWC member and by model implementation date (i.e. April 1 vs. July 1) and are summarized in the sections below.

April 1 Forecast

April forecast natural flow supply models were developed using data from 1990 through 2013. Data from 2014 was excluded from model development for two reasons: 1) the dataset for 2014 was still provisional at the time of model development and 2) record rainfall in August of 2014

resulted in significant data anomalies. For these reasons, we decided to exclude 2014 values from the dataset.

Both single linear regression and multiple linear regression models were considered. We recommend that natural flow supply forecast for A&B and Milner continue to be based on single linear regression models, in which the natural flow at the Snake River near Heise is the predictor variable. We believe the natural flow at the Snake River near Heise is a good predictor because A&B and Milner have relatively junior water rights and typically only divert natural flow during the spring runoff events. When applied, the April 1 forecast will utilize the U.S. Army Corps of Engineers and U.S. Bureau of Reclamation joint forecast of total natural flow in the Snake River near Heise from April-July. Alternative models were evaluated, but we found they added additional complexity without significantly improving the existing A&B and Milner models.

New multiple linear regression models are recommended to replace the existing regression models for TFCC, AFRD2, BID, MID, and NSCC. For these entities, the final predictor variables selected for their respective April 1 models included the total April through July natural flow in the Snake River near Heise and the total November to March discharge at Box Canyon Springs. The predictor variable, natural flow in the Snake River near Heise, was considered a good indicator of the natural flow supplied by snowmelt runoff. The predictor variable, Box Canyon Springs, was considered a good indicator for the natural flow supplied by the reach gains in the Blackfoot to Milner reach. If applied, the April 1 forecast models will utilize the U.S. Army Corps of Engineers and U.S. Bureau of Reclamation joint forecast of the natural flow in the Snake River near Heise from April-July.

Below is a table comparing the models used in the current Methodology to the recommended models. The recommended models for each member of the SWC have a better model fit (higher adjusted r^2) and a lower standard error than the models used in the current Methodology.

SWC Member	Models from Current Methodology[1]		Recommended Models	
	Adjusted r^2	Standard Error	Adjusted r^2	Standard Error
AFRD2	0.8317	39,700	0.8448	37,290
BID	0.7964	20,690	0.8546	17,100
MID	0.7896	29,710	0.8786	22,070
NSCC	0.8952	63,580	0.9151	55,950
TFCC	0.5416	71,990	0.8564	37,940

Appendix A contains graphs of the April models in comparison to the actual natural flow diversions for each SWC member.

July 1 Forecast

Step 6 of the Methodology requires the Department to issue a revised forecast supply "approximately halfway through the irrigation season". New natural flow predictor models have been developed for each SWC member for the specific period July 1 – October 31. We recommended that the July 1 models be implemented when revising the forecast supply in Step 6 of the Methodology.

Using data from 1990 to 2013, regression models were developed for A&B, AFRD2, and Milner by comparing snow water equivalent at the Two Oceans Plateau SNOTEL site on July 1 to the total

[1] Final Order Regarding April 2014 Forecast Supply, April 18, 2014.

natural flow diverted for the period July 1 through October 31. Data from 1997 was excluded from model development because of significant data anomalies as of a result of the high runoff year. The snow water equivalent at the Two Oceans Plateau SNOTEL site was considered a good indicator of additional natural flow diversions after July1. Years with zero (0) snow water equivalent on July 1 were excluded from the model dataset. It is recommended that in years with zero (0) snow water equivalent at the Two Oceans Plateau SNOTEL site on July 1, the predicted natural flow supply for the period July 1 – October 31 for A&B, AFRD2, and Milner will also be zero (0). For A&B, AFRD2, and Milner, the regression models would only be used in those years when the July 1 snow water equivalent at the Two Oceans Plateau SNOTEL site is greater than zero.

Multiple linear regression models were developed for BID, MID, NSCC, and TFCC. The regressions for BID, MID, and NSCC were developed with data from 1990 to 2013 and correlations were developed between the total natural flow diversions from July 1 through October 31and three predictor variables: (1) natural flow in the Snake River near Heise (April – June), (2) snow water equivalent at the Two Oceans Plateau SNOTEL site on June 15, and (3) March depth to water at well 05S31E27ABA1. Manual well measurements were historically taken from March 13 to March 30, with an average date of March 23. A transducer installed in May 2010 replaced the need for manual measurements. The combination of historical manual measurements and March 23 transducer readings will be utilized in the models.

The regression model to predict TFCC natural flow diversions from July 1 through October 31 relies on data from 1990 to 2013 and utilizes three predictor variables: (1) natural flow in the Snake River near Heise (April – June), (2) snow water equivalent at the Two Oceans Plateau SNOTEL site on June 15, and (3) Spring Creek total discharge (January – May). Below are summary statistics for the recommended models.

	Regression based on Two Oceans Plateau Snow Water Equivalent		Multiple Linear Regression	
SWC Member	Adjusted R^2	Standard Error	Adjusted R^2	Standard Error
A&B	0.9294	741		
AFRD2	0.8699	7,502		
BID			0.8932	11,480
Milner	0.8382	2,939		
MID			0.9037	15,720
NSCC			0.8615	46,930
TFCC			0.8511	29,270

Appendix A contains graphs of the July predictor models in comparison to the actual natural flow diversions for each SWC member.

Section 2 – Current Crop Mix Data

Current Method

Crop mix is one of the variables used in the current Methodology to calculate the crop water need of the SWC members. Crop mix is defined as the acreage of each crop type grown by each SWC member. The current method for determining crop mix is a three step process:

1) Tabular crop acreages from 1990 to the present are downloaded by county from the USDA National Agricultural Statistics Service (NASS).

2) Based on the tabular data available from 1990 to the present, an average crop mix for each county is determined.

3) The average crop mix of the counties is applied to each SWC member based on the proportion of land the SWC member has in each county.

Shortcomings of the current cropping pattern method include: NASS tabular data is adjusted to protect farmer privacy and is becoming increasing incomplete with fewer acreage totals being reported since 2005, average acreages for a 25-year period do not reflect current crop mix patterns, and county-wide crop mix may not represent the crop mix of SWC members.

Recommended Revision

Based on testing and with consideration of input from the committee, we recommend revising the method for determining crop mix. Instead of relying on county-wide tabular data, we propose using the digital Crop Data Layer (CDL) from the USDA National Agricultural Statistics Service (NASS). Benefits of this proposed method include: (1) using the most recent data available; and (2) restricting the geographic area of the data to the service area of each SWC member. The proposed method would involve the following steps each year:

1) Downloading the digital CDL dataset from the NASS website.

2) Removing crop type classification errors (speckling) in the CDL dataset with Zonal Statics in ArcGIS. A potential source of error associated with the Zonal Statics process is the intermittent availability of an annual field boundary dataset. However, our review of field boundary datasets and historical aerial photography revealed that field boundaries change infrequently and substituting field boundary datasets from previous years introduces minimal error. An additional possible source of error associated with the Zonal Statics process is the assignment of a single crop type to fields actually planted with multiple crop types. With respect to this concern our qualitative review of historical aerial photography and CDL datasets establishes that fields with multiple crops are rare and we conclude this concern represents a minimal source of error.

3) Clipping the CDL dataset in ArcGIS with an irrigated lands dataset for each SWC member.

4) Calculating the acreage by crop type for each SWC member.

5) Computing a 3-year average by crop type for each SWC member. In our analysis we have found the seven years of CDL data that are currently available do not depict a clear relation between cropping pattern and water supply. Because of this finding, a 3-year average appears adequate to reduce the influence of a single year while still being representative of the current cropping pattern.

Our comparison of the results of the tabular and CDL methods establishes that making this revision will cause the percentage of crop types identified for each SWC member to change between 0 and 30 percent (table below). This range of adjustment appears plausible given the change from a 20-year to a 3-year average and from a county-wide geographic area to the service areas of SWC members. A preliminary comparison of the crop water need calculated using the CDL and METRIC indicates the CDL and METRIC are in general agreement.

Section 3- Reasonable In-Season Demand (RISD)

The committee began discussions on improving the mid-season reasonable in-season demand forecast. With the limited timeframe the committee was given, we were unable to conclude an analysis of methods to improve RISD forecasts. Because this analysis is not yet complete, we cannot currently recommend any changes to the current Methodology regarding this issue.

Section 4 – Future Committee Meetings

Committee members provided valuable technical input for revising the Methodology. We recommend continuing to convene this committee in the following manner:

1) At least one annual meeting to review implementation of the Methodology during the previous irrigation season. This would be an ongoing forum for identifying and reviewing potential technical revisions to the Methodology.

2) Multiple meetings during 2015 to finish reviewing the following subjects that were discussed by the committee, but require further discussion and analysis to develop a recommendation:

    a. Mid-season calculation of reasonable in-season demand (RISD): The current method uses average demand in 2006/2008 to predict the RISD for the remainder of the irrigation season. We are analyzing the potential for refining this predication by selecting a representative historical analogous year(s).

    b. Supplemental ground water use: There was insufficient time for the committee to evaluate this subject.

    c. Project efficiency: The project efficiency variable used in the RISD calculation has not been updated since the Methodology was originally developed. The committee had preliminary discussion about the need to update project efficiency and committee members expressed interest in providing input.

    d. Irrigated acres: Significant discussion focused on this topic and it was generally agreed that the process for determining irrigated acres for SWC members could be improved.

APPENDIX B

Comments Received From Committee Members

MEMORANDUM
Settlement Document Subject to I.R.E 408

To: Liz Cresto

From: Charles Brendecke and Sophia Sigstedt

Subject: Comments on Staff Recommendations

Date: March 16, 2015

This memorandum addresses our comments on the analyses presented to the Technical Working Group related to revisions to the Methodology Order for determining injury to water rights held by members of the Surface Water Coalition. It serves as an addendum to the Idaho Department of Water Resources (IDWR or Department) staff memorandum regarding recommended revisions. Department staff were asked to provide recommendations to the Director on the following topics[1]:

1. Revised natural flow forecast methods for Twin Fall Canal Company (TFCC).
2. Identify more current and accurate crop data to determine crop water need.
3. Improvement of mid-season reasonable in-season demand forecast (RISD).

Topics 1 and 2 were assigned priority and due to time constraints are the only topics the Department staff make recommendations on in their memorandum.

Sections 1 and 2 below summarize our comments based on the proceedings of the committee regarding the recommendations to topics 1 and 2, respectively, in the staff memorandum. It is our understanding that Department staff recommendations on topics 1 and 2 are based on analyses that could be completed within the time constraints provided, and that while they are intended to provide guidance for administration of TFCC's water rights for the 2015 irrigation there will be opportunity for further analyses and recommendations concerning both topics for future irrigation seasons. It is also our understanding further work will be done on topic 3 prior to the need for the mid-season adjustment. Section 3 summarizes our preliminary comments regarding aspects of the mid-season RISD calculation.

The three topics identified above are not the only items in the Amended Methodology Order that were set aside or remanded by the District Court. The comments in our memorandum should not be considered a comprehensive summary of our opinion on all the technical aspects under consideration in the remand of the Amended Methodology Order.

---

[1] Status Conference, January 28th 2015

Section 1

Part D. of the Memorandum Decision and Order on Petitions for Judicial Review of the Amended Methodology Order found that "The *Methodology Order's* reliance upon the Joint Forecast, and its use of the Heise Gage, to determine the available water supply for Twin Falls Canal Company is set aside and remanded for further proceedings as necessary." The issue was unopposed and the Department expressed that the Joint Forecast is "not the best evidence" for purposes of predicting TFCC's supply and that they would be willing to work with TFCC to improve the predictors for future application.

The Department staff's recommendations for revised natural flow forecast methods for TFCC began with the assumption that the need to predict TFCC's supply must occur prior to April 1. The comments provided here neither support nor reject that assumption. The Department staff' recommendations for revising TFCC's supply improves the current relationship used in the Methodology Order. However the analysis and committee review process was undertaken in a highly compressed timeframe and many things warrant additional consideration. We support the idea of treating the refinements to the Methodology Order as a "living document" that allows for continual improvement and to use the staff's recommendation as an interim solution for the upcoming 2015 irrigation season only.

We believe that one reason the Heise Gage forecast is not a good predictor for TFCC supply is that the predictor is physically based while the TFCC supply is considered to be the historical TFCC diversion record. TFCC diversions are not the same as the physical supply available to TFCC because the diversions reflect administrative and operational influences in addition to being a condition of the physical natural flow supply. For example, TFCC has the more senior water right relative to the other surface water diverters below Blackfoot and their diversions in early season are often capped by the water right amount rather than the physically available supply. The water right cap creates a non-continuous and non-normally distributed dependent variable in the regression analysis. This difference is a probable reason the Heise forecast alone had such a low correlation to TFCC compared to the other entities. In light of this, an approach that we believe should be further investigated is creating a regression relationship or alternative model that forecasts the physical natural flow supply with subsequent allocation of that physical supply among the rights of the SWC.

The natural flow forecasts for TFCC and subsequently a selection of other entities were improved by moving from a single variable linear regression model to a multilinear regression. The improvement in the TFCC prediction supports the Department staff recommendation in the use of the additional Box Canyon data in April and the Snotel and Spring Creek discharge data in July. The Department Staff also recommended new models for some entities that showed improvement in the July forecast with the addition of Snotel and March groundwater level data. While these newly developed models can be tested over the upcoming irrigation season we believe they can be further improved.

Section 2

Our comments are limited on the succinct issue of the Department staff recommendation to use the digital Crop Data Layer (CDL) from the USDA National Agricultural Statistics Service (NASS) as a more current and accurate crop data source to determine crop water need. One concern here is how the data is post processed. We recommend sensitivity tests to different program settings when raster processing is applied. We also recommend further investigation into the method behind the development of the NASS dataset to determine how and to what extent the data set is field verified or if there are common misrepresentations that should be considered in the process of data quality assurance checks.

Section 3

As the Department memorandum stated there was not sufficient time for the staff to make a recommendation on the RISD forecast. There are multiple components to the RISD forecast calculation that are under review in the current Methodology Order. These include but may not be limited to:

- The mid-season calculation of RISD
- Project efficiency
- Irrigated acres
- Supplemental groundwater use

Regarding the mid-season calculation of RISD the sensitivity and appropriate use of crop coefficients and climate data behind the reference ET in the calculation should be investigated and analyzed for proper application to local conditions.

Regarding project effiencies we recommend investigation into trends among the entities related to each of the factors the Methodology Order considers in their determination.

Regarding irrigated acres it appears there is not a standard review process for the updates by the SWC or for the critique by IDWR of the submittal of the irrigated acres. With only a check against the total acres in the decreed place of use, there is little or no incentive to keep these shapefiles up to date. Based on the discussion in the technical working group the determination of irrigated acres will likely not be addressed in this review process. Updating irrigated acres by verification of claimed irrigated polygons by satellite and/or aerial imagery is a detailed, time consuming process. But it is essential to protect the valid water rights of juniors.

If SWC members are going to be responsible for this task a first step that the Department should take is to develop a standardized method for this update. This should include pointers to the preferred irrigated polygon base layer, satellite/aerial imagery, and a comprehensive list of items that need to be clipped out (i.e. roads, homesteads, brush land, fallow acres, water features, urban areas, sub-divisions), how alignment issues could be improved and recommendations for how to streamline as many of these processes as possible. This process will only be fair if each user does the analysis in the same way. Once a more accurate representation of the irrigated acres for each entity is created and approved updates in the future can be based more on accounting of the movement of water throughout the district as some of the entities already track. The 5% change standard should also be considered in light of large districts like TFCC where a 5% error

in irrigated acres can result in calculation of tens of thousands of acre-feet of erroneous mitigation obligation.

Regarding supplemental groundwater use there was not sufficient time for the working group or Department staff to address this issue. However, it was one of the specific technical items cited for revision by the District Court. Accordingly, we believe that the process that has been established for identifying Methodology revisions be continued until all the technical issues presented in the remand are addressed.

SPF WATER ENGINEERING

MEMORANDUM

DATE: March 16, 2015

TO: Liz Cresto, Technical Hydrologist

FROM: Scott King, P.E., SPF Water Engineering LLC on behalf of IGWA

RE: **Comments on Staff Recommendations**

Job: **535.0190**

Liz,

This memo provides comments to be included with your March 16, 2015 Settlement Document Memorandum.

1. The committee discussed the importance of methodology guidance being a living document and that the Technical Working Group (TWG) should continue meeting occasionally to improve the methodology and address items that were neglected due to limited time. I want to express my support for this approach.

2. Supplemental ground water use was a topic of importance to the Technical Working Group's (TWC), but was not evaluated sufficiently due to time constraints. Supplemental ground water use within much of the surface water coalition's delivery area is measured and reported to IDWR. However, we expect not all ground water use is measured due to the wells being located outside of the ground water measurement program area. Unmeasured supplemental ground water use should be addressed and may need to be measured.

3. The total area of lands receiving surface water irrigation deliveries has been updated for some but not all SWC members. The TWC discussed a methodology whereby irrigated acres would be updated if that area changed more than five percent from currently used values. A five percent change is significantly different when comparing between the smaller and larger delivery entities. For example, five percent approaches ten thousand acres for Twin Falls Canal Company. The committee may consider also including an acreage threshold in this decision point. For example: "the lesser of five percent or one thousand acres." This approach is supported by high quality aerial imagery currently available, limited land use changes within the SWC areas, and prior efforts in identifying and digitizing irrigated and non-irrigated areas.

300 E. Mallard Drive, Suite 350, Boise, Idaho 83706 Tel: 208-383-4140 Fax: 208-383-4156

4. Some delivery entities have reported that irrigated acres are unchanged from decreed values. There is not an incentive for SWC entities to identify and report reductions in irrigated acres. This deficiency should be addressed.

Thank you for the opportunity to participate in the committee and provide these comments.

Memorandum Subject to I.R.E. 408

To: Gary Spackman, Director IDWR

From: Charles G. Brockway, Brockway Engineering on behalf of the SWC
David Shaw, ERO Resources Corp. on behalf of the SWC

Date: March 16, 2015

Re: Recommended Revisions to the Second Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover

The SWC generally supports the efforts of the Director, IDWR Staff and other members of the TWG for their efforts and the recommendations proposed in the staff memorandum to the Director dated March 16, 2015. The recommended natural flow forecasting methods and crop mix determination are improvements to the original methodology procedure and we urge the Director to implement those changes. We also support the annual review of the implementation of the Methodology.

In the second paragraph under the April 1 Forecast section the statement is made that A&B and Milner irrigation districts have relatively junior priority water rights and typically only divert natural flow during spring runoff events. We believe it would be worth noting that Milner's priority is good enough to sometimes divert natural flow at other times, particularly late in the irrigation season.

The SWC supports the use of the NASS CDL data to estimate crop mix for the current year based on the 3 previous years' data. We notice in the example on page 6 of the staff memo the average used is for 2011 – 2013. We assume this is the result of a timing issue since the 2014 CDL was not released until after January 1, 2015. We assume the intent is to use the most recent 3 years' data when used to calculate RISD in the Methodology process. We also want to ensure the SWC Managers can submit crop mix data that becomes available to them if they believe any particular year is an anomaly and would not be fairly represented by the previous 3 years' CDL data.

The SWC is concerned about the topics in the final recommendation for multiple meetings for the remainder of 2015. Most of the proposed topics are not part of the Court's remand order. In particular, project efficiency was fully supported by the court in spite of the ongoing efforts by others to attack that aspect of the methodology or the efficiencies themselves. On remand the Court simply said the Director should follow the order when considering irrigated acreage submitted by members of the SWC. We understand the need to change the water supply forecasting methods to make a mid-season determination and the July 1 methods in the staff memorandum address that need but there has not been a compelling reason given to change the method of estimating demand for the remainder of the year.

Again, thank you to everyone who participated and to the Director and his staff for the opportunity to participate in this effort.

ATTACHMENT B:

LYNKER MEMORANDUM: COMMENTS ON 2022 IDWR STAFF RECOMMENDATIONS

MEMORANDUM

To: Matt Anders and Kara Ferguson, IDWR

From: Sophia C. Sigstedt, Lynker

Subject: Comments on 2022 IDWR Staff Recommendations

Date: January 16, 2023

This memorandum addresses my comments on the analyses presented to the 2022 Technical Working Group (TWG) related to revisions to the Methodology Order for determining injury to water rights held by members of the Surface Water Coalition. It serves as an addendum to Idaho Department of Water Resources (IDWR or Department) staff recommendations for the 2022 Methodology Update. IDWR staff and other members of the TWG presented analyses and recommendations regarding the following topics:

1. Baseline Year (BLY)
2. Forecasting Natural Flow Supply
3. Near-Real-Time METRIC for ET
4. Project Efficiency (PE)
5. ESPAM2.2 Steady State v. Transient

IDWR staff proposed changes related to BLY and PE, but only presented the results of internal analysis without recommending changes to the other topics investigated. TWG members were asked to consider whether the proposed recommendations provide a better technical basis than the current technique, or if there was an alternative with a better technical basis.

Sections 1-5 summarize my comments based on the proceedings for each TWG topic as listed above, respectively.

The topics identified above are not the only items in the Amended Methodology Order that should be considered regarding technical improvements. The comments in this memo are primarily in response to recommended changes made by IDWR staff in their memorandum dated December 23rd, 2022[1] and should not be considered a comprehensive summary of my opinions on all the technical aspects presented to the TWG or any other outstanding issues in the proceeding.

Section 1: Baseline Year Update

The IDWR staff recommended:

- Update the BLY irrigation demand used to determine Reasonable In-Season Demand (RISD) from the current average of diversion demands for the 2006, 2008, and 2012 (06/08/12) irrigation seasons to the diversion demand for the 2018 irrigation season.
- Update the BLY irrigation demand used to determine Reasonable Carryover for each SWC member from the current average of diversion demands for the 06/08/12 irrigation seasons to the diversion demand for the 2018 irrigation season.

[1] Summary of Recommended Technical Revisions to the 4th Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover for the Surface Water Coalition (IDWR, December 23rd 2022)

Lynker
5445 Conestoga Court, Suite 100
Boulder, Colorado 80301

In my opinion the recommendation to replace average diversions for the 06/08/12 irrigation seasons with single-year diversions in 2018 as the BLY does not have an adequate technical basis, and alternatives should be considered due to the following:

1. IDWR should consider rank within the period-of-record (POR) and select an average of years closer to the rank of the 06/08/12 BLY selected in 2015. IDWR staff presented analysis to the TWG for individual years 2018 and 2020 for consideration as the updated BLY. Either of these individual years are inadequate to represent reasonably dry baseline conditions for SWC diversions.

   When the average of diversion demands for the 06/08/12 irrigation seasons was selected as the BLY in 2015, the 06/08/12 average ranked between 7th and 8th highest for diversions, or about the 55th percentile (based on a normal distribution), for the POR 2000-2015 (**Figure 1**). IDWR staff presented analysis of Demand Shortfall calculations using 2018 and 2020 as an alternative BLY as they were both found to individually meet all the BLY criteria as shown in **Table 1**. For the POR 2000-2021 the diversion demand for 2018 and 2020 rank 3rd and 2nd, respectively, highest for diversions out of the 22 years, or about the 90th and 95th percentile (based on a normal distribution) for the POR (**Figure 2**).

   In a hindcast analysis by IDWR staff, the higher rank in BLY SWC diversions appears to cause a huge shift in the type of water year (i.e. wet, average, dry, very dry) where Demand Shortfalls are calculated. The hindcast showed a Demand Shortfall much more frequently in average and even wet years in addition to every dry or very dry year. When you compare the distribution of SWC total diversion demands for the POR 2000-2015 compared to 2000-2021 in **Figures 1** and **2**, however, it is apparent that they are very similar with mean diversions of 3.16 maf and 3.2 maf, respectively. The standard deviation is also very similar for the POR 2000-2015 compared to 2000-2021 at 178,089 af and 178,587 af, respectively. The selection of the BLY is meant to be conservative as defined by the BLY criteria. The shift to SWC diversions of a much higher rank (compared to the previous BLY) like 2018 or 2020 translates to a much higher level of conservatism and is not technically justified given the similarity between mean diversions and the standard deviation for the 2000-2021 POR versus the 2000-2015 POR.

   The Methodology Order states that the BLY can be a year or an average of years that meet the BLY criteria (**Table 1**). IDWR staff considered rank within the POR when they recommend keeping the 2002 and 2004 average Heise natural flows as the Supply in the Reasonable Carryover calculation from the 4th Amended Methodology Order for the 2022 update[2]. The average of diversion demands for the 2006 and 2018 (06/18) irrigation seasons meet all the BLY criteria as shown in **Table 1** and is closer to the 55th percentile based on a normal distribution for diversions 2000-2021 similar to the rank of the BLY 06/08/12 (**Figures 1** and **2**) as applied in the 4th Amended Methodology Order. The BLY of 06/18 has a better technical basis than the proposed update to 2018 as the BLY.

Table 1. Baseline Year and Baseline Year Criteria

BLY Criteria	BLY Avg 06/18	BLY 2018	BLY 2020	Avg 2000-2021
Abv Avg SWC Diversions	3.22 maf	3.38 maf	3.53 maf	3.20 maf
Abv Avg GDD	2575 units	2550 units	2600 units	2495 units
Abv ET	1265 mm/d	1275 mm/d	1280 mm/d	1245 mm/d
Blw Avg Precipitation	3.9 in	2.6 in	2.7 in	4.5 in
Abv Avg SWC Supply	8.52 maf	9.00 maf	8.10 maf	7.70 maf

[2] Proposed Modification of the Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover: Reasonable Carryover (IDWR, presentation slide no. 4, December 9th, 2022)

Lynker
5445 Conestoga Court, Suite 100
Boulder, Colorado 80301

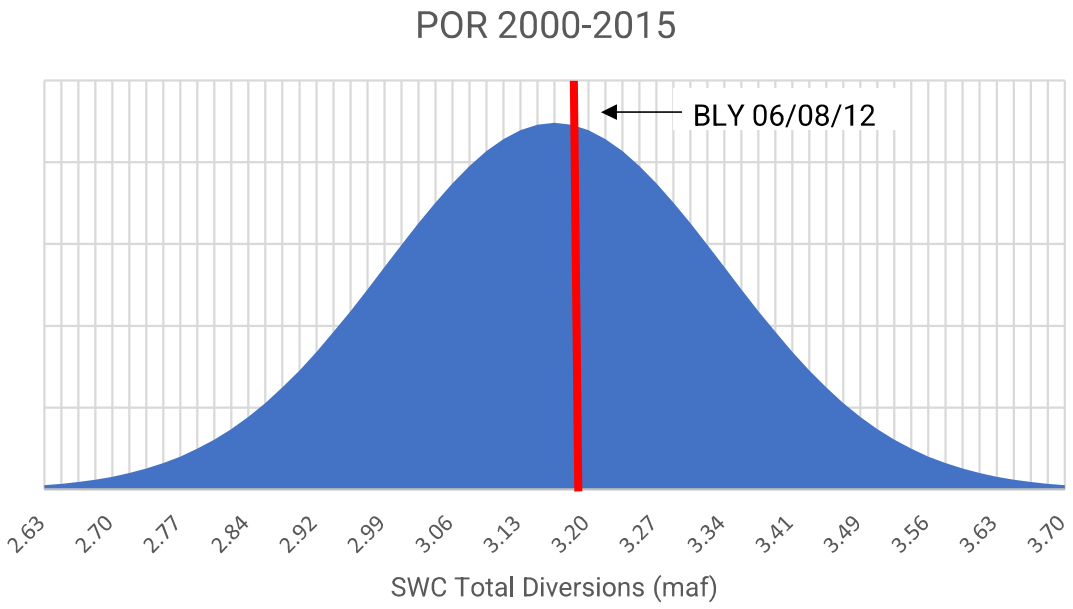

Figure 2. Normal distribution of SWC Total Diversion over the POR 2000-2015, the *red line* shows where the selected BLY 06/08/12 for the 4th Methodology Order falls within the normal distribution.

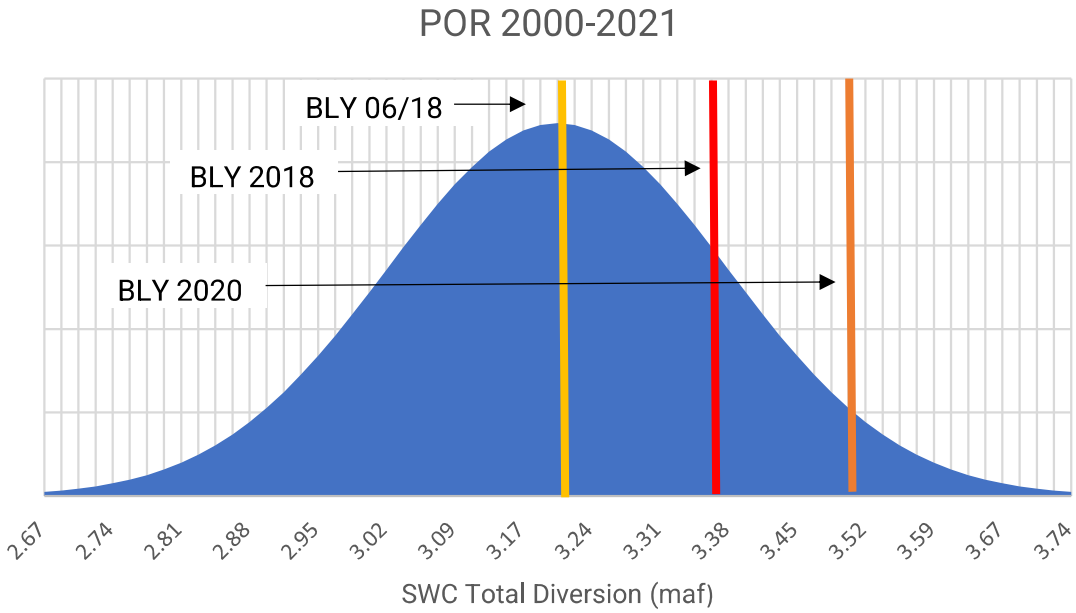

Figure 2. Normal distribution of SWC Total Diversion over the POR 2000-2021, the *yellow line*, *red line*, and *orange line* show where the proposed BLY 06/18, 2018 and 2020 falls within the normal distribution, respectively.

Lynker
5445 Conestoga Court, Suite 100
Boulder, Colorado 80301

2. Another reason a better alternative would be to use diversion demands for the 06/18 irrigation seasons for the BLY is that there were unique hydrologic circumstances in 2018 that I don't believe represent the typical dry year. The 2017/2018 snowpack was very high and water year forecasts and early season streamflow led to positive water supply forecasts which resulted in a record amount of aquifer recharge in 2018. IDWR staff acknowledged the technical difficulties in sorting out surface water adjustments like recharge in applying the Methodology Order. The combination of large volumes of widely distributed canal recharge, often in relatively rarely used or new systems, may have exacerbated uncertainty in the adjustment. The positive water supply outlook may have also resulted in less stringent surface water administration and ultimately higher diversions than the crop water need alone would predict. Consequently, using gross diversions in 2018 as the BLY effectively overstates surface water irrigation demand. IDWR staff presentations and a review of Twin Falls Agrimet station data also showed the 2018 irrigation season is the only year in the 1992-2021 POR with a zero-precipitation total for July-September. The fact that almost any individual water year will have some unique circumstance is a good reason for continuing to define the BLY based on an average of years as the Methodology Order does currently.
3. An additional reason for using a specific percentile (or rank) within the POR when establishing a BLY, and for using an average of years, is that the process for selection of the BLY otherwise appears arbitrary and subjective. If IDWR staff are presented with multiple years within the POR that fit the criteria for a BLY, and there is no guidance or standard method for selecting a single BLY, the ultimate selection becomes purely subjective. Using an average of years that targets a prescribed rank is a more objective and technically defensible process.

Section 2: Forecasting Natural Flow Supply

IDWR staff did not make a recommendation on updating April and July regression models to improve their predictive power for natural flow supply. The staff did make presentations to the TWG on natural flow forecasting models that showed the Twin Fall Canal Company (TFCC) model is degrading in the R^2 value. This degradation is significant in that the R^2 values is an expression of the explanatory power of the forecast model. The TFCC natural flow forecast models also started with the lowest R^2 values based on the previously revised forecast. The technical information presented to the TWG indicated that a revised natural flow method for TFCC should be evaluated and a recommendation for an improved method should be made. However, given the extremely compressed timeframe for staff and TWG members to conduct a thorough evaluation I understand why a recommendation was not made at this point.

Lynker's technical memorandum included as addendum to IDWR staff recommendations in 2015[3] laid out an alternative forecast model approach that I continue to think should be further investigated. The approach is creating a regression relationship or alternative model that forecasts the physical natural flow supply with subsequent allocation of that physical supply among the rights of the SWC. The technical basis for this suggestion is that water rights administration creates a non-continuous and non-normally distributed dependent variable in the regression analysis. This is likely the reason it is difficult to find a high performing regression model for TFCC.

The process for natural flow forecast model revision should also be standardized in-terms of defining how frequently a thorough re-evaluation of the predictors and models is done (i.e. 3-yrs, 5-yrs, if R^2 value drops below a threshold). This should include re-evaluating previously tested predictors over the new POR, as well as, casting a new net of total predictors for consideration by the TWG. While the TFCC model stands out in needing a refinement all of the models could be improved if sufficient time for the analysis were allowed. Several of the models utilize a depth to groundwater measurement as a predictor from a specific Sentinel Well flagged by a separate TWG (IGWA-SWC)[4], as likely impacted by American Falls Reservoir level.

[3] Recommended Revisions to the Surface Water Coalition Methodology (DWR, March 16th, 2015)

Lynker
5445 Conestoga Court, Suite 100
Boulder, Colorado 80301

Section 3: Near-Real-Time METRIC for ET

The IDWR staff did not make a recommendation on utilizing near-real-time METRIC for determining Crop Water Need (CWN) in the RISD calculation. The application of METRIC in the determination of crop demands deals with a complex dataset that requires complex processing. Given the magnitude of the task to incorporate METRIC data I understand the staff not making a recommendation at this time. The IDWR staff should keep track of the calculation utilizing the METRIC data in parallel to the current CWN calculation method as way to continue to evaluate its use. The Department's Eastern Snake Plain Aquifer (ESPA) model already utilizes METRIC data for consumptive use calculations used for model input data. Given the complexity of the METRIC data I also recommend further investigation into the method behind the calibration and processing of the dataset to determine how and to what extent the METRIC data can be validated at the field-scale or if there are common misrepresentations that should be considered in the process of data quality assurance checks. This should be done in coordination with validation efforts by the Department on their ESPAM Metric calibration and processing.

The IDWR staff presentation regarding near-real-time METRIC application identified a significant shortcoming in the current method for calculating CWN as the fact that the most up-to-date crop data is from the previous year and that SWC irrigated acre datasets sometimes represent service areas, not the actual irrigated land[5]. Non-irrigated acres should not be considered in determining the irrigation supply necessary for SWC members[6]. The METRIC data could first be used to create a standard review process for the Methodology Order Step 1 submittal of irrigated acres by the SWC entities. IDWR staff should use a precise determination of irrigated acreage irrespective of whether it uses METRIC in the calculation of CWN. With IDWR staff only checking against the total acres for the decreed place of use, there is little to no incentive to keep the spatial data for the irrigated acres up to date. The METRIC data would be available for the current irrigation season and can be used to assess actual irrigated land. Some of the preliminary analysis by IDWR staff using METRIC data illustrated that through processing they were able to identify about 15,000 acres within the TFCC irrigated acres dataset that should not qualify as irrigated. The mischaracterized acres were all minor areal corrections but over a large service area such as TFCC added up to a significant amount of erroneous total acres. This just highlights the importance of spending the time to get an accurate picture of irrigated acres for an accurate RISD calculation. As previously noted in Lynker's 2015 comment letter the 5% change standard for SWC submittals should be reconsidered in light of large districts like TFCC where a 5% error in the irrigated acres can result in calculation of tens of thousands of acre-feet of erroneous mitigation obligation. Liz Cresto an IDWR staff member on the TWG in 2015 also made a similar recommendation in her comment letter attached to the staff memorandum.

Neither the 2015 nor the 2022 TWG has provided an opportunity to address concerns regarding supplemental groundwater use. This is a critical aspect of the RISD calculation and was one of the specific technical items cited for revision by the District Court. Analysis of supplemental groundwater use is likely critical to accurately applying METRIC in the RISD calculation.

Section 4: Project Efficiency

The IDWR staff recommended:

- Update the project efficiency value used to calculate monthly reasonable in-season demand from a rolling average of the previous eight years to a rolling average of the previous fifteen years.

[5] Proposed Modification to Method for Determining Reasonable In-Season Demand for the Surface Water Coalition: Use of the Near Real Time Metric (IDWR, presentation slide no. 8, November 17th 2022)

[6] Second Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover-pg 4

Lynker
5445 Conestoga Court, Suite 100
Boulder, Colorado 80301

The technical basis for the IDWR staff recommendation was based on there being an extended POR available. TWG discussions and subsequent presentations identified other issues that should be considered in Methodology applications of project efficiency (PE) to RISD calculation.

1. There is higher uncertainty in the April and October project efficiency values. April and October represent months during the irrigation season when the method of calculating RISD strictly as a function CWN and PE is less reliable because CWN is often not the driving factor in diversions[7].
2. Project efficiency among SWC entities are almost all flat or declining (6 out of 7 entities), which is contrary to what would be expected with technology advancements and constrained water supplies[8].

Change in Project Efficiency (2001-2021) (percentage point change)	
A&B	-4.6%
AFRD2	-3.6%
BID	-1.0%
Milner	-12.6%
Minidoka	+12.2%
NSCC	-3.0%
TFCC	+1.8%

3. Scatter plots by SWC entity comparing Annual Crop Water Need to Annual Diversions show Crop Water Need is limited as a predictor given the low explanatory power indicated by the low R^2 values in the analysis[9].

Regarding the mid-season calculation of RISD, the sensitivity and appropriate use of CWN as a predictor for in-season demands for SWC entities should be evaluated. Technical analysis to the TWG showed that this is not a strong relationship[10]. This disconnect should be evaluated by the TWG so a recommendation can be made. The trends in declining PE are concerning in that they are contrary to our expectations given the direction technology advancements and constrained water supply. The declines in PE are significant in that any decline in PE will result in increased demands and subsequently increased calculated Demand Shortfalls. The IDWR staff presentation on PE illustrated how the very minor change in PE resulting from extending the POR for the average translated to tens of thousands of acre-feet differences in the Short Fall determination[11]. Sullivan (e-mail to TWG 12/21/2022) found that when analyzing monthly PE the low PE in some months cause monthly demands calculated based on CWN/PE to be very sensitive to changes in CWN. I agree with Sullivan's recommendation that given the outside influences and uncertainty in some of the monthly PE values IDWR staff should consider using a seasonal PE value in computing monthly diversion demands. I also agree with Sullivan's recommendation that consideration should be given to PE values that better reflect reasonable and efficient operations of SWC members. Given the observed declining trends in PE and the historically wide range in operational PE by entity it is hard to know when SWC supplies are short under reasonable and efficient operations. This is consistent with Lynker's 2015 recommendation for an investigation into trends among entities related to PE factors.

Boulder, Colorado 80301

Given the compressed timeframe around the 2022 TWG meeting there was not sufficient time for the TWG members to analyze or address these outstanding issues. Additional time should be set aside for the TWG to conduct an analysis and make a recommendation.

Section 5: Steady State v. Transient

The Department staff did not make a recommendation on using transient model simulation for determining curtailment priority dates in the Methodology. The IDWR staff presented to the TWG the following:

1. Technically the steady state application is not consistent with the variable curtailment dates and mitigation volumes under the Methodology.
2. Transient analysis shows that in-season shortfalls can generally not be met at Time of Need by in-season curtailment.
3. There is a huge difference in resulting determination of the curtailment priority date if a steady state v. transient model is applied.
4. Under a transient model application any Demand Shortfall above ~100K af would result in aquifer wide curtailment

It is not clear what additional analysis the Department staff need to conduct to make a recommendation on steady state v. transient model application. What is clear is that this represents a huge uncertainty to the water users and how they make planning and management decisions moving forward.

1.0 INTRODUCTION

1.1 Objectives

The objective of this report is to review the hydrology, water rights and groundwater modeling of the Eastern Snake Plain Aquifer (ESPA) in the vicinity of the Rangen, Inc., (Rangen) aquaculture facility, as they relate to the delivery call placed by Rangen on December 13, 2011. That delivery call requests the curtailment of all groundwater rights within the domain of the Enhanced Snake Plain Aquifer Model (ESPAM) that are junior to July 13, 1962. The primary study area of focus of this report is shown on Figure 1.1.

1.2 Organization of Report

This report is organized into 6 sections, beginning with this Introduction and Summary of Conclusions. Section 2 presents an overview of hydrology and water development in the area of the Rangen facility. Section 3 provides a detailed description of the Rangen facility itself and the water rights pertinent to it. Section 4 describes development and calibration of the ESPAM Version 2.1 (ESPAM2.1) by the Idaho Department of Water Resources (IDWR). Section 5 describes analysis of the effects of curtailment of junior groundwater rights using ESPAM2.1 and its predecessor, ESPAM2.0. Section 6 presents an analysis of curtailment effects using a modified version of ESPAM2.1 that more closely reflects hydrogeologic conditions near Rangen.

A related discussion of hydrogeology of the Rangen area is presented in Hinckley (2012).

1.3 Summary of Conclusions

Based on the analyses and evaluations I carried out in preparing this report, I conclude that:

1. The Martin-Curren Tunnel is a distinct source of water separate from natural springs that also supply Rangen.
2. The July 13, 1962, Rangen water right that is the basis of the delivery call (36-2551) is sourced at the Martin-Curren Tunnel.
3. The April 12, 1977, water right (36-7694) held by Rangen is sourced at the Martin-Curren Tunnel.
4. The Martin-Curren Tunnel is an artificial excavation that was constructed to access groundwater for irrigation purposes.
5. The Martin-Curren Tunnel meets the physical definition of a well contained in Idaho Code 42-230(b).
6. Neither observed nor estimated flows from the Martin-Curren Tunnel have ever been high enough to provide water in-priority to the 1977 water right (36-7694) held by Rangen.
7. Observed flows of Billingsley Creek reported by Rangen have not been high enough to provide any water to Rangen's 1977 water right (36-7694) since October of 1976, a date which precedes the priority of the water right.
8. Inspection of Rangen facilities and diversions by the Department of Water Resources concluded, among other things, that water right 36-7694 "should not have been issued."

9. Water right 36-7694 has never been able to divert and beneficially use water in priority.
10. Neither observed nor estimated flows from the Martin-Curren Tunnel have ever been high enough to deliver the maximum rate of diversion authorized under water right 36-2551.
11. Rangen's measurement of water flows through its property underestimates actual flows by 10-12%
12. It is feasible for Rangen to make more efficient use of available flows by delivering water from Billingsley Creek to its small raceways.
13. As a result of incidental recharge from surface water irrigation, spring flows in the Milner to King Hill reach are currently 25 percent greater than natural, pre-development flows.
14. Much of the change in spring discharge in the Milner to King Hill reach since 1960 can be attributed to reduction in incidental recharge from surface water irrigation due to changes intended to reduce waste.
15. Neither ESPAM 2.1 nor its predecessors is capable of separating the effects of groundwater pumping on flows from the Martin-Curren Tunnel from the effects of groundwater pumping on flows from other springs in the Rangen complex. .
16. The predictive uncertainty analysis of ESPAM2 and ESPAM2.1 carried out by the IDWR explores only a limited aspect of model uncertainty and does not quantify overall model uncertainty.
17. Fundamental to overall model uncertainty is the uncertainty associated with the conceptual model reflected in ESPAM2.1. The predictive uncertainty analysis relies on a single conceptual model and does not explore the uncertainty that arises from improper conceptualization of local geologic and hydraulic conditions that influence discharge of specific spring complexes, such as those at Rangen.
18. Alternative conceptual models can be developed that better reflect hydro-geologic conditions near Rangen and which produce substantially different effects of curtailment than does ESPAM2.1.
19. That ESPAM2.1 can fairly closely mimic the observed past behavior of a spring complex is not proof that it represents hydrogeologic reality sufficiently to predict accurately future behaviour of that complex, especially under aquifer water use conditions (e.g., curtailment of junior groundwater pumping) that are radically different from those extant in the model calibration period.
20. The ESPAM2.1 is not sufficiently detailed in either its general formulation or its representation of hydrogeologic conditions at Rangen, to be used reliably to predict changes in flow available to water right 36-2551 due to curtailment of junior groundwater rights on the ESPA.
21. ESPAM2.1 represents the details of the Rangen spring complex and the surrounding geology in highly simplified form, omitting several key features and that would make significant differences in predicted benefits of curtailment.
22. Using ESPAM2 and ESPAM2.1, less than 3 % of the curtailed groundwater rights junior to Rangen's 1962 priority, under the 10% trimline, would accrue to the Rangen complex; the rest would accrue to other connected river reaches, springs and baseflows, including those on which there are no water rights or diversions, those on which there are no delivery calls, those on which

approved mitigation plans are already in place, and those on which diversions occur under water rights junior to those of the curtailed rights.

23. An even smaller amount of the curtailed water use described in conclusion (23) above would accrue to the Martin-Curren Tunnel.

24. Using ESPAM2, less than 1% of the curtailed groundwater rights junior to Rangen's 1962 priority over the entire model domain, such as requested by Rangen, would accrue to the Rangen complex, the rest accruing to other connected river reaches, springs and baseflows, including those on which there are no water rights or diversions, those on which there are no delivery calls, those on which approved mitigation plans are already in place, and those on which diversions occur under water rights junior to those of the curtailed rights.

25. Because the model domain, irrigated lands and water rights are the same in ESPAM2.1 as in ESPAM2, conclusion (25) above would also apply to results from ESPAM2.1.

26. An even smaller amount of the curtailed water rights described in conclusion (25) above would accrue to the Martin-Curren Tunnel.

27. Alternative calibrated models that better reflect hydro-geologic conditions near Rangen show that curtailment of groundwater rights, within the 10% trimline and junior to Rangen's 1962 right, would produce only half, and possibly as little as 5%, of the benefit to Rangen predicted by ESPAM2.1.

28. Analysis using ESPAM2.1 shows that implementation of Rangen's request for widespread curtailment will, by any reasonable standard, result in waste of the water resource.

29. If the Director uses ESPAM2.1 to quantify the benefits to water right 36-2551 from curtailment of junior groundwater uses, this quantification should reflect the substantial uncertainty of that benefit that derives from use of a regional model to predict discharge from a particular spring outlet at the edge of the aquifer system. Due to this uncertainty, any curtailment based on ESPAM2.1 should be limited to junior-priority rights for which ESPAM2.1 predicts a significant benefit to Rangen. In my opinion, to recognize uncertainty and prevent unreasonable waste, application of ESPAM2.1 should at a minimum restrict curtailment to junior rights for which ESPAM2.1 predicts at least 10% of the curtailed water will accrue to Rangen.

30. Even use of a 10% trimline results in waste of the water resource because the vast majority of that foregone use would not accrue to the benefit of Rangen.

31. Use of trimlines smaller than 10% increases the relative waste of the water resource.

Hydrology and Water Development

32. Spring discharge is closely related to incidental recharge from surface water irrigation within the service area of the North Side Canal Company.

33. The sensitivity of spring discharge to incidental recharge is likely increased near the edges of the aquifer system near the Hagerman Rim and Rangen.

34. The Winter Water Savings Program of the North Side Canal Company alone may have reduced incidental discharge to the ESPA above the Thousand Springs reach by roughly 150,000 acre-feet per year beginning in 1961.

35. Conversion of irrigated lands from flood and furrow irrigation to sprinkler irrigation has significantly reduced incidental recharge.

36. Sprinkler usage under the North Side Canal Company grew from zero percent of the service area in 1982 to 100% of the service area by 2008.

37. Approximately 24,000 linear feet of lateral off the W-canal in the area west of Wendell, in proximity to Rangen, have been lined or placed in pipe since the 1990s, primarily to reduce excessive seepage losses, which are incidental recharge.

38. All of the foregoing reductions in incidental discharge are reductions in waste of water.

39. Prior to development of irrigation under the North Side Canal Company natural flow from springs in the Milner to King Hill reach was estimated to be about 4,000 cfs. Spring flows reached a peak at about 7,000 cfs in the early 1950s and have declined since that time. The average annual discharge for the 10-year period ending in 2011 is about 5,000 cfs, which is still above the natural (predevelopment) levels

40. When significant surface water irrigation began in the NSCC area the seasonal variability of spring discharges increased in addition to the magnitude of average annual flows. Prior to development, the pronounced seasonal pattern of spring flows that currently exists did not appear to exist.

41. Reductions in total annual spring discharge are also related to drought episodes.

Rangen Water Use

42. Discharges from the Curren Tunnel are divided between Rangen pipelines, three irrigation diversions, and spills to Billingsley Creek from the Rangen Box.

43. The North Snake Groundwater District has been providing mitigation supplies to the irrigation water users through the Sandy Pipeline since 2003. This pipeline is believed to have nearly eliminated irrigation diversions from the Curren Tunnel outlet.

44. Flows in Billingsley Creek are divertible by gravity to Rangen's large raceways but not to the hatch house, upper (small) raceways, or culinary use, all of which are presently supplied only by pipelines from the Tunnel.

45. Spills from the Rangen Box may remain in Billingsley Creek and bypass the Rangen facilities under some circumstances.

46. It is feasible to pump water from Billingsley Creek to Rangen's small raceways from the same point where Rangen diverts water into the large raceways. This would increase the efficiency of use of Rangen's existing physical supplies by making the total discharge of the Rangen complex available to all of Rangen's raceways.

ESPAM2.1 Model

47. Observations of ESPA geology suggest it is highly complex, comprised of overlapping fractured basalts interspersed with sedimentary formations, with hydraulic characteristics that can vary substantially over short distances.

48. ESPAM2.1 is, like all models, a simplified representation of reality, and this leads to model uncertainty.

49. ESPAM2.1 is comprised of cells that are one mile square.

50. Within each ESPAM2.1 grid cell, aquifer characteristics are assumed to be homogenous and isotropic.

51. This assumption of homogeneity means that hydrologic and geologic details of a scale smaller than the cell cannot be explicitly represented in the model.

52. Considerable amounts of pertinent input data are not known at even the one-square mile level of spatial resolution of the ESPAM2.1 grid.

53. ESPAM2.1 is comprised of a single layer of cells of uniform thickness.

54. ESPAM2.1 assumes constant thickness throughout the model domain and constant transmissivity within each cell. These assumptions may result in substantial misrepresentation of flow conditions in some parts of the aquifer, such as the Hagerman rim, where thinning occurs and preferential flow pathways become more restricted.

55. The discharges at Rangen are represented in ESPAM2.1 as a single drain.

56. This single-drain representation does not allow ESPAM2.1 to distinguish flows emanating from the Curren Tunnel from flows emanating from natural springs in the Rangen complex.

57. The generalizations and simplifications in ESPAM2.1 can introduce significant error into model results, particularly for highly localized conditions such as those governing discharge from specific outlets of a specific spring complex.

58. ESPAM2.1 has a large number of cells and each cell has a large number of adjustable parameters, so the total number of adjustable parameters in the ESPAM2.1 model is large.

59. The large number of parameters reflected in ESPAM2.1 increases the likelihood that the model is not unique.

60. ESPAM2.1 simulates conditions that are not physically possible and conditions that are in direct opposition to observed conditions in the real system. These discrepancies reveal serious model misrepresentation of detailed aquifer behaviour in the Rangen area, and raise doubt as to the accuracy of model predictions there.

61. Many of the conceptual aspects of ESPAM2.1 fail to reflect observed characteristics of the aquifer system in the Rangen area. These failures lead to conceptual uncertainty in the ESPAM2.1.

62. Each of the input data types used in ESPAM2.1 carries its own uncertainties that can stem from, among other things, the inability to measure a condition accurately (or at all) and from the spatial or temporal resolution of measurements.

ESPAM2.1 Calibration

63. Calibration uncertainty reflects the fact that many combinations of model parameter values may lead to equally well-calibrated models.

64. The ESPAM2.1 was calibrated under the assumption that aquifer transmissivity in any given cell is constant over the calibration period. This assumption has not been validated, and there are many locations and situations in the model domain and over the model calibration period where it is probably not true.

65. ESPAM2.1 was calibrated using an automated approach implemented in a computer program called PEST.

66. ESPAM2.1 systematically under-estimates discharge at the Rangen spring in the early years of the calibration period while over-estimating it in the later years.

67. ESPAM2.1 systematically under-predicts the water level at the closest well to Rangen that was used for calibration by 20 feet. ESPAM2.1 also consistently under-predicts the water level in another nearby well.

68. The under-prediction of water levels near Rangen is partly a result of the fact that discharge targets were weighted more heavily than water level targets in the calibration process.

69. Because predicted water levels are too low, PEST increased the drain conductance to values higher than are suggested by observation, thereby embodying in ESPAM2.1 a mischaracterization of the real physical relationship between water levels and flows at Rangen.

70. This mischaracterization results in over-sensitivity of the change in drain flow to a simulated change in water level due to curtailment. This over-sensitivity is carried into the superposition model used for curtailment, with the result that changes in spring flows are over-predicted by nearly a factor of 4.

71. The calibrated drain conductances in ESPAM2.1 range over 4 orders of magnitude. This extremely large variation suggests that the set of calibrated parameters is quite fragile and that PEST can readily find alternative parameter sets that provide acceptable calibrations.

72. ESPAM2.1 differs from ESPAM2 in the correction of an error that arose in the calculation of the water budget in the Mud Lake area and overestimated aquifer recharge by approximately 89,000 acre-feet/year in that area of the model domain. This represents a change of less than one percent in the overall water balance for the ESPA.

73. Correction of this error required re-calibration of the model, so a new set of model parameters, including drain conductances were developed. These are the parameters used in ESPAM2.1.

74. The drain conductances in ESPAM2.1 differ from those used in ESPAM2 by more than the 1% change in water budget associated with the correction. The conductance for the Rangen drain decreased by about 4%, but some drain conductances in the area changed by nearly 1000%. Some cell transmissivities in the area near Rangen changed by more than 100%.

75. These changes in conductance and transmissivity are carried directly into the superposition models used to calculate the flow changes resulting from curtailment.

76. The area encompassed by the 5% trimline is substantially larger with ESPAM2.1 compared to ESPAM2, and this expansion is mainly in areas on the opposite side of the Malad Gorge from Rangen, which are hydrogeologically disconnected from the Rangen spring.

77. Large changes in calibrated parameter values and model results suggest that ESPAM2 and ESPAM2.1 may be over-parameterized, and that other comparable calibration solutions easily can be reached with only minor perturbations in model assumptions.

Estimation of Benefits from Curtailment

78. ESPAM2.1 represents the Rangen spring as a drain and the flow in that drain as a linear function of water level in the cell that contains the drain.

79. Application of ESPAM2.1 to estimate changes in spring flow due to curtailment employs the method of superposition.

80. The principle of superposition relies on the assumption that the system being modeled and the model behaves in a completely linear way.

81. If the system being simulated or the model exhibits important non-linear behaviours, a superposition model can introduce significant error into the analysis of effects of stress changes.

82. Analysis of observed water levels and Range spring flows by Hinckley demonstrates that the relationship of Rangen flow to water levels in nearby wells is not linear.

83. The structure of the aquifer and conditions in the aquifer along the Hagerman Rim in the region of Rangen indicate that the behaviour of the aquifer in that region is not linear.

84. The large number of parameters reflected in ESPAM2.1 increases the likelihood that the model is not linear.

85. There are a total of 406 groundwater irrigated acres relying on rights junior to Rangen's 1962 priority within the 10% trimline, using 1,445 acre-feet of groundwater. At steady state, curtailment of pumping on these lands would cause total modeled flow at the Rangen springs to increase by 0.19 cfs (141 af/y assuming year around flow). Not all of this increase would accrue to the Martin-Curren Tunnel, but the ESPAM2.1 model does not represent flows in the tunnel. It would take somewhat less than a year for discharge to reach 90% of this modeled steady state increase.

86. There are a total of 565,023 groundwater irrigated acres within the model domain relying on rights junior to Rangen's1962 priority, using 1.46 million acre-feet (MAF) of groundwater. At steady state, ESPAM2 predicts that curtailment of pumping on these lands would cause modeled discharge at Rangen to increase by 18.07 cfs. It would take approximately 16 years for modeled discharge to reach 90% of this steady state increase.

87. Because the model domain, irrigated lands and water rights are the same in ESPAM2.1 as in ESPAM2, conclusion (86) above would also be expected to apply to results from ESPAM2.1.

2.0 WATER DEVELOPMENT AND USE ON THE EASTERN SNAKE PLAIN

2.1 Hydrology

The Snake River flows along the southern edge of the Eastern Snake River Plain (ESRP), a broad arcuate plain that covers an area of approximately 10,000 square miles in southeastern Idaho. As shown on Figure 2.1, the two main branches of the Snake River are the South Fork, which primarily drains the eastern side of the Teton mountain range, and the Henry's Fork, which primarily drains the western side of the Teton Range and joins the South Fork near Idaho Falls. Several smaller tributaries enter the Snake River from the south, the largest being Willow Creek and the Blackfoot, Portneuf and Raft rivers. With few exceptions, tributaries from the mountains to the north of the plain flow out onto the plain and recharge the underlying aquifer. Because of its porous surface, there are no significant surface water features on the plain itself.

At Milner Dam, northeast of Twin Falls, the Snake River drops into a canyon making gravity diversion of river flows impossible; large irrigation canals at Milner seasonally divert all but a small amount of the river flow. The canals diverting from the Snake River at Milner Dam, as well as others diverting from the lower Big and Little Wood Rivers, deliver large amounts of irrigation water to lands in Jerome, Gooding and Lincoln Counties above the north rim of the river canyon. The Snake River itself is largely restored by the time it reaches King Hill due to spring discharges from the north wall of the Snake River canyon and tributary streams such as Rock Creek, Salmon Falls Creek and the Malad River.

The ESRP is underlain by a vast basalt aquifer system, the Eastern Snake Plain Aquifer (ESPA), formed when intermittent lava flows filled ancestral valleys and canyons of the Snake River (Stearns and Crandall, 1938). In the central part of the ESPA, these and other formations extend to a depth of more than 3,000 feet (Whitehead, 1992). The total volume of water stored in the ESPA has been estimated to be as high as 1 billion acre-feet (IDEQ, 2006).

The agriculturally productive areas of the Plain occur in sedimentary and aeolian deposits overlying the most recent (Quaternary) basalts, which outcrop in numerous places. The porous and fractured basalt formations in the upper part of the ESPA can store and transmit large amounts of water and have been developed as a groundwater resource. Lindholm (1996) estimated that the upper 500 feet of the aquifer may contain 200-300 million acre-feet, an amount approximately 50 times greater than the combined surface water storage above King Hill.

Between Milner Dam and King Hill are numerous springs that emerge from the north side of the canyon and flow to the river. In some cases there are very well-defined outlets for these springs while in other cases they discharge through talus slopes and the actual outlets in the canyon wall can't be seen. There are also some springs that emerge in the river itself. This reach of the river is often referred to as the Thousand Springs Reach, though there is also an individual spring complex named Thousand Springs. A few of the larger spring complexes along the north wall of the canyon are at Crystal Springs, Clear Lakes, Box Canyon, Thousand Springs, Billingsley Creek and the Malad Gorge.

Figure 2.2 shows the annual average water budget for the period 1981-2008 used in development of the ESPAM2.1. Note that this is not a water budget for the ESPA, as it includes surface water supplies that are consumed directly without entering the aquifer. Based on Figure 2.1, average recharge to the aquifer system from precipitation on non-irrigated lands, from tributary underflow, and from non-Snake River seepage is 2.46 million acre-feet (MAF). This relatively small component of overall aquifer recharge is still greater than the total groundwater consumption simulated in curtailment to 1870 (Sukow, 2012) indicating that groundwater use remains less than the reasonably anticipated rate of future natural recharge.

2.2 North Side Canal Company

Early irrigation development on the ESRP was concentrated in the upper portions of the basin, above Blackfoot. Irrigation development in the lower portion of the plain began in 1877 with appropriations from the lower Big and Little Wood Rivers north of Wendell and Shoshone. By 1900, surface water rights totalling more than 900 cfs had begun operating to irrigate lands above the Malad Gorge (at their confluence, the Big and Little Wood Rivers become the Malad River).

Diversions from the Snake River onto the western ESPA began in 1905 with the development of the Twin Falls Project. Small diversions by the Twin Falls North Side Land & Water Company (predecessor to the North Side Canal Company) began in 1908. Diversions quickly grew from 250 thousand acre-feet (KAF) in 1909 to 1.2 million acre-feet (MAF) in 1912 (USGS, 1956). Considerable water was diverted in the first decade of canal operation to fill the Jerome Reservoir, but that project was abandoned in 1918 after it became clear that seepage losses from the reservoir would prevent it ever being filled (Crandall, 1923; USGS, 1956). North Side Canal Company (NSCC) diversions at Milner Dam have averaged about 986,000 af/y over the last 10 years. Present acreage served by the NSCC is reported to be 154,067 acres. Figure 2.3 shows the present service area and main canals and laterals of the NSCC.

For the first half of the 20th century, the NSCC diverted water in the winter as well as during the irrigation season. This was done primarily to provide domestic and stock water to small towns and farms. There is no significant crop water demand in the winter, so considerable amounts of the winter diversions undoubtedly recharged the ESPA in Jerome and Gooding Counties or were spilled over the canyon rim at the ends of laterals.

As part of its Regional Aquifer System Analysis (RASA) study, the USGS estimated that by 1952 more than 24 MAF of water had been added to the aquifer by incidental recharge from surface water irrigation (Kjelstrom, 1995). The importance of incidental recharge resulting from seepage losses from surface irrigation systems is evident in Figure 2.4a, b which is reproduced from the RASA study. Figure 2.4a shows the close correlation between incidental recharge and spring discharges in the Milner to King Hill reach of the river. The pattern of incidental recharge is clearly superimposed on a longer term increasing trend of spring discharge from 1912 to the mid-1950s, and is very closely related to the declining trend in spring discharge since the mid-1950s. Figure 2.4b shows the estimated change in ground water storage from this incidental recharge.

Figures 2.5 and 2.6 are from another RASA report (Goodell, 1988). Figure 2.5 shows the early 20th century increase in water levels in three observation wells, the locations of which are shown on Figure 2.6. Water levels in observation well 8S-17E-19BBB1 reflect water levels in the aquifer beneath the area irrigated by the North Side Canal Company. It can be seen that the aquifer water level in this area rose by approximately 45 feet between 1900 and 1950 as the result of incidental recharge from surface water irrigation.

Winter diversions all but ended in about 1960 as the Company participated in the Winter Water Savings Program, which sought to stop 435,000 af of "wasteful non-irrigation season diversions" and redirect this water to storage in Palisades and American Falls Reservoirs (USBR, 1946). The Palisades Winter Water Savings agreements went into operation in 1961 and generally required participating canal companies to cease diversions in the months of November through March. Figure 2.7 is derived from records of the USGS and the IDWR and shows the historical November through March diversions of the NSCC. The onset of the Winter Water Savings Program is clearly evident in this diversion record. Based on Figure 2.7, the Winter Water Savings of the North Side Canal Company alone may have reduced incidental recharge to the ESPA above the Thousand Springs reach by roughly 150,000 acre-feet per year (207 cfs).

Prior to the 1950s, flood and furrow irrigation was the primary method of water application on the ESRP. Kjelstrom (1995) notes that by the 1970s about 20 percent of surface water irrigation distribution systems had converted from gravity application methods to sprinkler application methods and that this conversion had reduced deep percolation to the aquifer. In 1981 the University of Idaho published (Hamilton, et al., 1981) the results of a survey of the responses of irrigators to the severe drought of 1977. Table 2.1 is reproduced from the Hamilton report. It shows that many irrigators on the ESRP had installed sprinkler systems, had added gated pipe, and had lined ditches as a result of the 1977 drought.

Information provided to the IDWR by the North Side Canal Company in connection with the 2005 delivery call of the Surface Water Coalition shows that in 2004 sprinklers were the primary method of water application on 88 percent of the North Side service area. Documentation for the current groundwater model of the Eastern Snake Plain Aquifer (ESPAM2.1) reflect a growth in sprinkler usage under the NSCC from 0% of the service area in 1982 to 100% by 2008. This has undoubtedly further reduced aquifer recharge in the area of the springs.

Figure 2.8 shows the portion of the NSCC service area generally between the town of Wendell and the head of Billingsley Creek. The irrigation laterals shown in this area are part of the W-lateral system. Lateral W-40 extends nearly to the head of Billingsley Creek, ultimately reaching a spill point on the canyon rim immediately to the north of the Rangen aquaculture facility. Recent data (Sullivan, 2012) show that flows into the lower portion of the W-lateral system, have declined about 20,000 af/y since the late 1980s. Interviews of NSCC personnel (Wertz, pers. comm., 2012) revealed that approximately 24,000 linear feet of laterals off the W-Canal in the area west of Wendell have been lined or placed in pipe since the 1990s, primarily to reduce excessive seepage losses.

The spill point at the end of W-40 was visited in June, 2012, and did not show evidence of current use. As with other canal companies in the area, the NSCC has been attempting in recent years to consolidate and reduce spills to the river for water quality management purposes. The primary spill point for the W-Canal system is now into the Malad Gorge just downstream of the State Park.

2.3 Springs in the Milner to King Hill Reach

As mentioned previously, between Milner Dam and King Hill the Snake River flows in a deep canyon. There are numerous springs discharging from the walls of this canyon, the majority of them being on the north side in an area known as the Thousand Springs reach, including an individual spring complex named Thousand Springs. In some cases there are very well-defined outlets for these springs while in other cases they discharge through talus slopes and the actual outlets in the canyon wall can't be seen. There are also some springs that emerge in the river itself. Figure 2.9 shows the locations of major spring complexes in the Milner to King Hill reach.

The earliest records of spring discharge measurements in this reach of the river date back to 1902. In the spring of that year the U.S. Department of Agriculture and the U.S. Geological Survey (USGS) separately made measurements on several of the springs in this reach of the river. These and other early measurements are summarized in Nace, et al., (1958). J.D. Stannard, the investigator for the Department of Agriculture estimated the total discharge of springs on both sides of the river between a point 3 miles above Twin Falls and a point 10 miles below the Malad River (roughly the entire Milner to King Hill reach) to be 3,833 cfs. These 1902 measurements were made before irrigation development under the North Side Canal system, though not before irrigation diversions began from the lower Wood River to supply lands north of Wendell and Shoshone. Kjelstrom (1995) estimated that the pre-irrigation (pre-1880) discharge of springs between Milner and King Hill averaged about 3.0 maf, or 4,140 cfs. Mundorff, et.al. (1964) estimated the natural discharge from the aquifer in the Thousand Springs Reach to be 4,000 cfs, and possibly less.

When significant surface water irrigation began in the North Side Canal area spring discharges changed, increasing in seasonal variability and in overall magnitude. Meinzer (1927) prepared an inventory and description of large springs in the United States, including the springs in the reach of the Snake River between Milner Dam and King Hill. Figure 2.10, reproduced from the Meinzer report, illustrates the close relationship he found between the combined spring discharges at the Blue Lakes and Clear Lakes spring complexes and the quantity of irrigation water applied to the Eastern Snake River Plain above the springs via the North Side Canal Company. Figure 2.10 shows that the monthly rise and fall pattern of North Side Canal diversion is followed, in a slightly delayed fashion, by a similar monthly pattern in spring discharge. Canal diversions were substantially smaller in 1919 (shortly after the Jerome Reservoir project was abandoned) than they were in the preceding two years, and the subsequent rise in spring discharge is also substantially smaller. A comparison of the two 1902 observations of flow at Blue Lakes given in Nace, one in April and one in August, showed almost equal flow rates. So the seasonal spring discharge pattern evident in the period 1917-1920 didn't appear to exist in 1902 at Blue Lakes and Clear Lakes, prior to major irrigation development above the springs. This emphasizes the importance of localized patterns of incidental recharge to flows of specific springs.

The IDWR prepares estimates of the annual spring discharge to the Thousand Springs Reach based on a method originally developed by Kjelstrom (1995b) and documented in USGS Water-Resources Investigation Report 95-4055. Figure 2.11 is a plot of the discharge estimates prepared by the IDWR for the period 1902-2011. The average of the annual discharge values for the 10-year period from 1902-1911 is 4,207 cfs. The average annual discharge for the 10-year period ending in 2011 is 5,019 cfs.

Also shown on Figure 2.11 is the annual value of the Palmer Drought Severity Index (PDSI) for NOAA Climate Zone 7 (NOAA Earth System Research Laboratory Physical Sciences Division 2012). The PDSI is a commonly used water supply index that incorporates precipitation, temperature, runoff and soil moisture conditions. Greater positive values of the PDSI reflect increasingly cooler and wetter conditions; greater negative values reflect increasingly warmer and drier conditions. A relationship can be seen in Figure 2.11 between drought episodes and reductions in total estimated spring discharge to the Milner to King Hill reach.

From the foregoing, it can be concluded that pre-development springs flows in the Thousand Springs Reach were probably not greater than 4100 cfs; that flows peaked in the early 1950s at approximately 6900 cfs primarily as a result of surface water irrigation development; and that flows have declined to current levels as a result of changes in surface water irrigation practices, drought and groundwater development. However, spring discharge between Milner and King Hill remains above natural (predevelopment) levels.

2.4 Groundwater Development

With the exception of shallow wells constructed in the Mud Lake area in the 1920s, ground water development of the ESPA did not begin in earnest until the late 1940s. The first project relying heavily on ground water supplies was the Minidoka North Side Pumping Division of the Minidoka Project (now the A&B Irrigation District) which began operation in 1948. While the majority of the subsequent permits were for irrigation of new lands, many were for supplemental irrigation of lands already irrigated with surface water supplies. In addition, the benefits of sprinkler irrigation have led to the conversion of some formerly surface-water irrigated lands to ground water use. Ground water development began to level off in the 1980s and a moratorium on new irrigation well development has been in place since 1992.

Farms in the Wendell area were initially supplied with irrigation water by the NSCC (Sullivan, 2012). Conversion of irrigated lands from surface to groundwater sources and development of new groundwater-supplied lands in the area began in the 1950s. Figure 2.12 shows the growth in groundwater permits in the area from 1948 until 1992, when a moratorium on further groundwater irrigation permitting went into effect. Notable increases in permitting occurred in 1960-61, just prior to Rangen's application for water right 36-2551, and in 1973-76, just prior to Rangen's application for water right 36-7469. Figure 2.13 shows the current Points of Diversion for groundwater rights in the area between Wendell and the head of Billingsley Creek; these points are color-coded to show their priorities relative to July 13, 1962.

Sullivan estimates that there were approximately 25,000 acres of irrigated land under the W Canal in 1953 and about 30,500 acres in 2009. In 1953 there was little or no groundwater irrigation under the W Canal. By 2009 roughly 10,000 of the formerly surface-water irrigated acres were supplied in whole or in part with groundwater and about 9,300 acres of new acreage was being served by groundwater (about 3,500 acres of surface water irrigation had been retired). Given the 1992 moratorium on new groundwater irrigation, it is reasonable to assume that nearly all of this groundwater use was actually in place by 1992.

Figure 2.14 shows observed groundwater levels in two wells in the area between Wendell and Rangen. Records of groundwater levels are less complete as one goes back in time, so the wells shown in Figure 2.14 do not illuminate aquifer conditions in earlier periods. It can be seen from Figure 2.14 that that seasonal fluctuations in water levels are about 5 feet in this area, with lows generally occurring in the months of March (well 992) and July (well 989). Annually, water levels have declined somewhat since 1985, with levels appearing more stable in the last 10 years. These declines are likely due to changes in surface water irrigation practices, including spill management, lining or piping of laterals, and conversions from surface to groundwater use, to drought, and to that increment of groundwater pumping brought online since 1985.

3.0 RANGEN SPRINGS DEVELOPMENT AND USE

3.1 Billingsley Creek Overview

Billingsley Creek enters the Snake River northwest of the town of Hagerman, just upstream from Lower Salmon Falls Dam. The creek is fed by a series of springs emanating from the Quaternary basalts forming the canyon rim in western Gooding County. Figure 3.1 is an aerial photo of the area showing the creek and the locations of selected spring discharge points. Figure 3.2 shows the measured flows of Billingsley Creek at the USGS gaging station (13134600) at the Highway 30 bridge just north of Hagerman. Records at this station are not continuous, and spring and creek flows are diverted both above and below the station for aquaculture, irrigation and other uses.

The Martin-Curren (aka Curran, Kearn) Tunnel and Rangen aquaculture facility are located at the upper end of Billingsley Creek. Figure 3.3 is an aerial photo of the Rangen facility showing key features of the area that will be referred to later in this section. Flows from the Tunnel and from other spring outlets and seeps in the Rangen area form the headwaters of Billingsley Creek.

The Rangen facility was constructed in 1962, apparently expanding on an earlier, smaller aquaculture operation purchased by Rangen in May of that year (Twin Falls Times-News, December 30, 1962). The facility was launched as a research center focused on trout diseases and diet, and on hatchery management problems.

The primary physical sources of water used at the Rangen facility are the Martin-Curren Tunnel and natural springs, most of which emerge from the talus slope about 45 feet in elevation below the tunnel portal (Farmer, 2009). Water from the Tunnel is divided between Rangen pipelines and three irrigation diversions. The natural springs all discharge to Billingsley Creek. Flows in Billingsley Creek are divertible by gravity to Rangen's large raceways but not to the hatch house, upper raceways, or culinary use, all of which are presently supplied only by pipelines from the Tunnel. Inspection of the Rangen facilities by IDWR personnel in 2003 concluded that some spring inflow to Billingsley Creek also occurs below the diversion for the large raceways (Berkey, 2003a).

3.2 Water Rights

Water rights for flows in the headwaters of Billingsley Creek in the area of the Rangen facility are listed in Table 3.1. The earliest rights date to 1884 and are for irrigation and domestic use.

The earliest right for fish propagation is Rangen's 1957 priority for 1.46 cubic feet per second (cfs). This may have been the primary water right for Rangen's predecessor. The present delivery call seeks administration of groundwater rights junior to Rangen's 1962 priority (36-2551), which is sourced by the Snake River Basin Adjudication (SRBA) Court at the Martin-Curren Tunnel.

The irrigation rights of Candy, Morris and Musser are also sourced at the Martin-Curren Tunnel. These diversions provide water to irrigate parcels south of Billingsley Creek. The water rights for these diversions are senior to the Rangen rights, dating to as early as 1884. Because the irrigation diversions are consumptive with respect to Billingsley Creek, they reduce the water supply available to Rangen from the Tunnel.

In 2003, anticipating that groundwater users might in the future be required to mitigate declines in Tunnel and spring flows, the North Snake Groundwater District (NSGWD) voluntarily constructed a pipeline (the "Sandy Pipeline") from ponds in Section 5 of T8S, R14E (the "Sandy Ponds") to the Curren Ditch. The pipeline was constructed so that it could also supply irrigation water to Candy, Morris and Musser, thereby reducing or eliminating those irrigation diversions at the Tunnel and increasing the Tunnel supply available for Rangen. This pipeline is in operation and is believed to have nearly eliminated irrigation diversions from the Tunnel outlet.

The Curren Ditch diverts from the creek below the Rangen facility under irrigation rights that are also senior to the Rangen aquaculture rights. However, since Rangen's aquaculture use is non-consumptive, the Curren Ditch does not call for bypass of Rangen's more junior aquaculture rights.

Groundwater development on the plain above the Curren Tunnel began in the early 1950's. Figure 2.12 showed the evolution of groundwater rights in the area east of Billingsley Creek. The earliest groundwater rights in the immediate area date to 1952. Notable increases in permitted acreage occurred in 1959-61 and in 1973-76, just prior to Rangen's applications for water rights 36-2551 and 36-7694. By the time of Rangen's 1962 water right, about 3900 acres had been permitted. At the time of Rangen's 1977 water right, about 8300 acres had been permitted. By 1992, when the moratorium on new groundwater irrigation went into effect, permits for about 10,000 acres had been issued.

3.3 Curren Tunnel Development

The Curren Tunnel is excavated into the canyon rim above the Rangen facility. It extends roughly 100-300 ft into the basalt forming the rim (Tate deposition testimony, 2012), at a depth roughly 70 feet below the ground surface above the rim (Hinckley, 2012). The tunnel is bifurcated some distance into the cliff into north and east forks. Water flows out of the Tunnel by gravity.

It appears that the Tunnel excavation had at least commenced by October of 1884 (New International Mortgage, 1932) with the aim to deliver irrigation water via a ditch (i.e., by gravity) to lands on the bench area south of Rangen. A feature article in the December 30, 1962, Twin Falls Times-News describes the source of Rangen's supply as "man-made springs on the north side of the canyon" where "early pioneers in search of irrigation water drilled a hole into the cliff and struck water." USGS Water Supply Paper 1463 (Nace, et.al., 1958) contains a Billingsley Creek flow observation made in April, 1902, with remarks that "Water emerges from a tunnel dug into brecciated, highly permeable basalt, and from the talus slope below the tunnel…" The 1932 decree from New International Mortgage Bank v Idaho Power Company, et.al., an adjudication of

water rights in Billingsley and Riley Creeks, grants 1884 priority rights to water "…developed and diverted…by means of a tunnel commonly known as the Curran Tunnel…".

According to Idaho Code 42-230(b) a "well" is defined as "an artificial excavation or opening in the ground more than eighteen (18) feet in vertical depth below land surface by which groundwater of any temperature is sought or obtained." Based on the foregoing descriptions of its development, the Curren Tunnel appears to meet this definition.

About the first 50 feet of the Tunnel is lined with large diameter corrugated steel pipe; beyond this the tunnel is unlined. It is not known when the corrugated steel lining was installed. A 6" diameter PVC pipe is laid along the bottom of the steel pipe, extending beyond it into the unlined portion to the bifurcation. This PVC pipe carries water for laboratory, culinary and landscape irrigation use at the Rangen facility. Based on a diagram produced by Rangen (RANGEN001907), it is believed that this PVC pipe was installed in 1976.

The PVC pipe does not carry all the water emerging from the Tunnel. The remainder of tunnel discharge is collected in a concrete division box (the "Farmers box") at the mouth of the tunnel, shown in Figure 3.4. The Candy, Morris and Musser pipelines deliver water from this division box to parcels south of the Rangen facility; the elevation of the Tunnel outlet allows this irrigation delivery to operate by gravity.

Two Rangen pipelines also take water from the Farmers box and water can spill from the box. The two Rangen pipelines flow into another concrete box, the "Rangen box" shown in Figure 3.5, which is further down the slope toward the Rangen facility. There they enter the pipeline serving the hatch house and research facility. Spills from the Rangen box, as well as flows from other spring outlets, flow into Billingsley Creek and can be diverted into Rangen's large raceways.

There are other spring outlets in the vicinity that also supply water to the Rangen facility. The largest of these emerges about 45 ft below the Curren Tunnel and flows to Billingsley Creek. Based on recent discharge records, discussed in more detail below, these "lower" springs produce roughly twice the flow of the Tunnel.

3.4 Discharge Records

The earliest record of discharge from springs in the Rangen area is contained in Nace (1958). Table 27 in that report shows a Billingsley Creek flow of 54.3 cfs in April, 1902, at a location where Road E2900S (aka Hagerman Highway) crosses Billingsley Creek. This observation post-dates the excavation of the Tunnel, and potentially includes discharges from other springs in the area. Other than a few subsequent measurements in the general vicinity, systematic recording of spring discharge in the area did not begin until the Rangen facility was operating.

The only measurement of discharge specifically from the Curren Tunnel was in the period between 1993 and 2009 when the IDWR operated a sonic measuring device inside the tunnel. This measured the portion of tunnel flow not conveyed in the 6" PVC pipe installed in the tunnel

by Rangen. All other historical measurements of spring discharge are derived from measurements made by Rangen at locations within the hatchery or on Billingsley Creek.

Flow measurement within the Rangen facility relies primarily on recording the depth of water flowing over the check dams in the "large" and "CTR" raceways, and depth of water flowing over the "lodge dam" in Billingsley Creek shown in Figure 3.6. Flow depth is apparently measured by a metal ruler placed on the crest of the dams as shown in Figure 3.7 (Exhibit 7a from Rangen 1st Request; Yenter, 2003). It appears that the flow from the CTR raceways reflects flow through the Rangen hatchery and, when combined with discharge over the lodge dam and diversions for irrigation, gives the total discharge of the spring complex.

Along with most other spring users, Rangen began submitting diversion records to the IDWR in 1995. In late 2003, responding to a request from IDWR Director Karl Dreher, Rangen submitted monthly flow records covering the period 1966-2003. These data, and the measurement methods used by Rangen, were subsequently reviewed by IDWR technical staff (Yenter, 2003; Berkey, 2003, 2003a). This review included field inspection of measurement sites and methods, and verification of various estimates used by Rangen in its flow summarization. The inspection concluded, among other things, that the flow record reflected total spring complex discharge rather than Rangen diversions and found that Rangen's flow measurement methods could underestimate the total discharge by 10-12%.

Figure 3.8 shows the IDWR records of total discharge from the Rangen complex, as well as observed flows from the Curren Tunnel and IDWR records for flow in the 6" PVC pipe from the Tunnel. Seasonal variability of flow is plainly evident as are longer term wet and dry spells. In the period of overlap between total flow and Tunnel flow records, it appears the Tunnel flow is the greater source of this seasonal variability. This is to be expected as the Tunnel penetrates the aquifer at a higher elevation than that of the natural springs. In his May 19, 2005, Order, former Director Dreher found decreases in the springs supplying the Rangen hatchery facilities to be correlated with repairs made to the facilities of the North Side Canal Company to reduce losses of surface water to ground water from the canal company's facilities above those springs in 1987, 1998, and 2000 (Order, FF 23). The 1992 moratorium on new irrigation wells suggests that decreases in discharge after the mid-1990's are not the result of groundwater pumping.

Figure 3.9 shows a regression analysis of total Rangen flow against observed Curren Tunnel flow. It can be seen that the relative contribution of the Tunnel is somewhat greater at higher total flow; this is to be expected from the relative elevations of the Tunnel and the natural springs that contribute to the total flow. At lower flow levels, the Tunnel may represent as little as 20% of the total Rangen flow. Over the last 10 years, the Tunnel discharge has represented roughly one-third of the total Rangen flow.

The regression shown in Figure 3.9 was used to generate estimates of Curren Tunnel flow for the entire period of record for Rangen total flow. The results of this procedure are shown on Figure 3.10, which plots both the monthly total Rangen flow and the monthly Curren Tunnel flow for the period 1966 through 2012. Also shown on Figure 3.10 are the cumulative water rights sourced at the Martin-Curren Tunnel by the Snake River Basin Adjudication (SRBA). The cumulative rights

at the Tunnel were 61.29 cfs prior to Rangen's April, 1977, appropriation. With that appropriation, cumulative rights at the Tunnel rose to 87.29 cfs.

It can be seen from Figure 3.10 that the flows from the Martin-Curren Tunnel have never been high enough to fully satisfy Rangen's 1962 priority (36-2551) and have never been high enough to provide any water to Rangen's 1977 priority (36-7694). Accordingly, it can be concluded that water was not available to water right 36-7694 at the time of its appropriation nor at any later time.

In his May 19, 2005, Order former Director Dreher found that the Department of Water Resources erred in licensing water right 36-7694 and should not have recommended it in the SRBA, because water was not available to it either at the time of its appropriation or subsequently (Order, FF 62, 63, 72). The foregoing analysis of Rangen discharge records shown in Figure 3.10 supports this conclusion.

Director Dreher also found that curtailment of water rights junior to July 13, 1962 (Rangen water right 36-2551) would "not at any time result in a meaningful increase in the quantity of water discharging from springs in the Thousand Springs to Malad Gorge reach of the Snake River, which includes the Curran Springs from which Rangen diverts surface water." (Order, FF 84). In its disclosure of June 12, 2012, the Department produced modeling results, apparently related to this finding, showing an analysis by Allan Wylie with a conclusion that Rangen could "at best expect" an increase of 0.22 cfs from curtailment.

A decomposition and back-casting of the historical monthly total discharge of the Rangen spring complex was also undertaken by Brannon (2009) apparently in anticipation of its use as a target for groundwater model calibration. This decomposition relied on Rangen measurements dating back to 1966. Figure 3.11 shows the results of this effort. Documentation of this work has not been provided by Rangen, though notes in the spreadsheet file submitted by Brannon to the IDWR allude to such documentation (Rangen Water History for IDWR.xls). Inspection of this decomposition supports the preceding conclusions that there has never been water available to water right 36-7694 since its time of appropriation.

While flows diverted from the Martin-Curren Tunnel can be delivered through the small raceways and reused in the large raceways, spring flows emerging below the Tunnel cannot. Based on a reconnaissance-level analysis (Coleman, 2012), it is feasible to pump water from Billingsley Creek to the small raceways from the same point where the diversion to the large raceways is made. This would increase the efficiency of use of Rangen's existing physical supplies by making the total discharge of the Rangen complex available to all of Rangen's raceways.

4.0 MODEL DEVELOPMENT

4.1 Background

The Enhanced Snake Plain Aquifer Model (ESPAM) is the current incarnation of numerical modeling of the Eastern Snake Plain Aquifer (ESPA) that began in 1974 (deSonneville, 1974). The ESPAM was created with review and input from the Eastern Snake Hydrologic Modeling Committee (ESHMC). The ESHMC is comprised of professionals working on water issues on the eastern Snake River Plain. Regular members include agency representatives (Idaho Department of Water Resources, U.S. Bureau of Reclamation, U.S. Geological Survey, U.S. Fish and Wildlife Service), industry representatives (Idaho Power), researchers (University of Idaho, Idaho Water Resources Research Institute) and private consultants representing various water user interests. While a diversity of interests are represented on the ESHMC, the committee is constituted by request and invitation and not through election or appointment on the basis of population, water right amounts, irrigated acreage, or other such factors. Committee decisions are generally reached by consensus, though this is not always possible to achieve.

Actual development of ESPAM was carried out by the IDWR and the Idaho Water Resources Research Institute (IWRRI). Model design, construction and calibration were reviewed and in some instances redirected by the ESHMC.

From the outset of the ESPAM modeling effort, it was recognized that there would be a need for future enhancements to the model as new information and modeling approaches became available. ESPAM Version 1.0 (ESPAM1.0) was released in 2004, followed shortly by ESPAM1.1 which corrected an input data error. Discussions regarding the scope of future enhancements to ESPAM1.1 began shortly after its release (e.g., Brendecke, 2009a). ESPAM2.0 was released in the summer of 2012; correction of an input data error has recently resulted in the distribution of ESPAM2.1.

4.2 Model Structure

4.2.1 Overview

Like its predecessors, the ESPAM2.1 is developed in MODFLOW, a groundwater modeling environment developed by the U.S. Geological Survey (McDonald and Harbaugh, 1988; 2000). In MODFLOW, aquifers are represented as a collection of rectilinear elements or “cells”. The MODFLOW code solves the equations of flow between these cells to determine how the aquifer will respond to changes in inputs or outputs. Figure 4.1 shows the grid of model cells used for ESPAM2.1.

Within each cell, aquifer characteristics (e.g., porosity, hydraulic conductivity) are assumed to be homogenous (the same throughout the cell) and isotropic (allowing flow to occur in all directions with equal ease) as would be the case if the cell were filled with clean sand of uniform grain size. This assumption of homogeneity means that hydrologic and geologic details of a scale smaller

than the cell cannot be explicitly represented in the model. MODFLOW has the capability to represent anisotropy (where flow occurs in preferential directions), but this feature has not been used in any versions of the ESPAM.

A MODFLOW model may be comprised of one or more vertical layers of cells. Multiple layers are typically used when there is more than one geologic layer that is meaningful to groundwater flow patterns. The thickness of cells in model layers can vary to reflect changes in thickness of subsurface formations, such as the thinning of water bearing formations that often occurs at the edges of aquifers.

Boundary conditions must be defined to characterize the patterns of flow into and out of the model domain, and MODFLOW provides a variety of special cell types for this purpose. River cells are used to represent subsurface flow between river reaches and the aquifer. Drain cells are used to represent aquifer discharge through springs. Constant flux cells are used to represent fixed amounts and patterns of subsurface flow into the aquifer from tributary valleys. Other special-purpose cells serve other functions.

Most of the cells in a MODFLOW model are general purpose cells. It is in these model cells that aquifer recharge from precipitation and irrigation, and aquifer withdrawals by pumping and evapo-transpiration, among other things, are represented. To carry out a groundwater flow simulation, it is first necessary to develop a water budget of aquifer inflows and outflows at each model cell and to develop, through calibration, estimates of parameters representing the aquifer characteristics at each cell.

4.2.2 General Structure of ESPAM2.1

Like its predecessors, the ESPAM2.1 is comprised of cells that are one mile square. This means that features having dimensions smaller than one mile cannot be explicitly represented in the model. However, considerable amounts of pertinent input data are not known at even this one-square mile level of spatial resolution. For example, subsurface geology on the ESPA is known with certainty only at outcrops or at locations where drilling logs are available. Crop distribution information on the ESPA is available only at a county level from annual agricultural statistics based on self-reported data. Detailed water distribution to lands within canal companies can be quite variable as shares are transferred between users; even if this information were readily available it is difficult to embody in model inputs. As a result of these latter data limitations, crop distributions in ESPAM2.1 are assumed to be uniform county-wide, and surface water distribution is assumed to be uniform across every parcel of served land within groups of canal companies.

The resolution of input data may not present a problem when doing a regional-scale analysis because local errors, if random, may effectively cancel each other in the larger context. However, the questions presented in the present delivery call are quite localized in nature and this “error cancelling” cannot simply be assumed to occur. Hinckley (2012) has illustrated some of the discrepancies that exist between the coarse simplifications of ESPAM2.1 and the details of Rangen-area hydrogeology.

Like its predecessors, ESPAM2.1 is comprised of a single layer of cells of uniform thickness. This means that substantial aquifer thinning, such as occurs in the Hagerman-Wendell, Burley-Pocatello, and Rigby Fan-Mud Lake areas (Whitehead, 1992), is not represented in the model. This is important because aquifer transmissivity (T) is a linear function of the hydraulic conductivity of the aquifer material (K) and the aquifer saturated thickness (b), as shown in the following equation:

$T = Kb$

As the aquifer material (in this case the Quaternary basalt) thins, the transmissivity is reduced and resistance to groundwater flow increases. Saturated thickness is also reduced by drawdown of the water table, e.g., by pumping or by spring discharge, resulting in a non-linear relationship between water level and flow. The ESPAM2.1 assumes constant transmissivity throughout the model domain. This assumption is made largely for reasons of computational convenience, as will be discussed later in this report, but may result in substantial misrepresentation of flow conditions in some parts of the aquifer, such as the Hagerman rim, where thinning occurs and preferential flow pathways become more restricted.

Like its predecessors, the ESPAM2.1 represents springs using special-purpose drain cells. As shown in Figure 4.2, discharge from a drain cell is a function of the difference in head (Δh) between the computed water level in the cell and the assumed elevation of the drain outlet, and a conductance parameter (C) that effectively acts as a throttle on the rate of discharge. The conductance parameter can be expressed in units of cubic feet per second (cfs) per foot of head difference. While it is a calibrated value in ESPAM2.1 (calibration is discussed in a later section), under certain conditions it can be estimated from field observations.

Like its predecessors, the ESPAM2.1 uses data from a variety of sources to represent the water budgets of the aquifer and of individual model cells. These data include precipitation, surface water diversions, subsurface inflows from tributary basins, stream gage records, county surveys of crop distributions, estimates of evapo-transpiration (ET), methods of irrigation water application, and assumptions about irrigation canal seepage, among others. With few exceptions, the data sources used in the ESPAM2.1 are the same as those used in its predecessors.

From the foregoing, it can be seen that the ESPAM2.1 should not be viewed as a new model of the ESPA but as a relatively modest refinement of earlier versions of ESPAM. It has the same conceptual formulation as its predecessors and relies on the same data sources as its predecessors. Its spatial resolution is the same as that of its predecessors. Like its predecessors it "…is a regional-scale model … best applied for regional-scale predictions." (IDWR, 2012).

4.2.3 Key Differences between ESPAM2.1 and Its Predecessors

The ESPAM2.1 utilizes a longer study period (1980-2008) than did ESPAM1.1 (1980-2002). The addition of six years to the study period means that more input data are used in the ESPAM2.1,

though the basic data sources used remain the same in both models. The ESPAM2.1 utilizes monthly stress periods where ESPAM1.1 used semi-annual stress periods; the increased number of stress periods also increased the amount of input data used in ESPAM2.1, since each formerly semi-annual data value was replaced with 6 monthly values. In some cases (e.g., precipitation, canal diversions) this allowed more accurate temporal representation of water budget terms, while in others (e.g., tributary underflow) it required further disaggregation of data for which only annual estimates are available.

Surface water conveyance and application efficiency are represented in more detail in the ESPAM2.1 than in ESPAM1.1. A greater number of leaky canals were explicitly represented in ESPAM2.1 (primarily in eastern portions of the plain), though canal seepage losses are still considered to be constant throughout the model study period. Farm irrigation efficiency is assumed to increase somewhat in water-short years in ESPAM2.1 through an "On-Farm Algorithm" that operates on model input data. Irrigated acreage is slightly higher in ESPAM2.1 due primarily to the use of better image processing methods than were used for ESPAM1.1 (Sukow, 2012).

The ESPAM2.1 is calibrated to a larger number of spring complexes in the Milner-King Hill reach of the Snake River than was ESPAM1.1. This stems largely from efforts to develop more complete data sets of spring discharges than were available for ESPAM1.1. In large part, these data sets are based on diversion and flow measurements reported by spring users, with extrapolation to fill missing data. The data sets were then used as targets for calibration of drain cells representing those spring complexes. Some spring complexes in ESPAM2.1 are represented by using two drains within the same model cell; in general, this was done to encompass the range of observed outlet elevations of springs falling within the cell, but in some cases the springs so represented may have little hydro-geologic relation to one another. Figure 4.3 shows the distribution of drain cells used to represent springs in the ESPAM2.1.

The more comprehensive representation of spring complexes in ESPAM2.1 necessitated the use of General Head Boundary (GHB) cells to represent observed river gains that were not accounted for in spring discharge data (Wylie, 2012 memo). These unaccounted for flows were implicit in ESPAM1.1 spring discharges. GHB cells work in a fashion similar to drain cells in that their discharge is a function of head difference and a calibrated conductance parameter. Figure 4.3 also shows the distribution of these GHB cells, some of which occur in cells already containing drains representing springs.

4.3 Rangen Area Representation in ESPAM2.1

While all the refinements made in ESPAM2.1 have some effect on simulated flows and impacts at the Rangen springs, two refinements bear directly on them. The first of these is the use of the Rangen springs as a specific calibration target in ESPAM2.1. Figure 4.4 shows a close-up of the ESPAM2.1 model grid in the area of the Rangen complex. In ESPAM1.1, flows at the Rangen springs were estimated as a percentage of overall spring discharge to the Thousand Springs - Malad subreach (the cells that comprised this reach are highlighted on Figure 4.4). In ESPAM2.1, historical diversions and Billingsley Creek flow measurements reported to the IDWR

by Rangen were used to derive estimates of monthly total discharge that were used as a calibration target. The discharges at Rangen are represented in ESPAM2.1 as a single drain, though discharges actually occur at multiple outlets. This single drain representation does not allow ESPAM2.1 to distinguish flows emanating from the Curren Tunnel from flows emanating from natural springs in the Rangen complex.

The second ESPAM2.1 refinement of particular consequence in the Rangen area is the elimination of the Hagerman Valley from the model domain. This was done at the recommendation of geologist Dennis Ralston, who studied the area and reported to the ESHMC that the Tertiary formations underlying the Valley were not connected to the ESPA (Ralston, 2008)[1]. As a result, the canyon rim became the westernmost extent of the model domain in the Hagerman area in ESPAM2.1. Figure 4.5 shows the changes in the model domain made with ESPAM2.1, highlighting the change in the Rangen area.

Later, after comparing the historical discharges of springs used for calibration targets with reach gains computed from river gages, it was discovered that the observed reach gains substantially exceeded, by roughly 25%, the sum of spring discharges used as calibration targets (Wylie, 2011; 2012 memo). To remedy this discrepancy, GHBs were defined through several reaches to account for the undocumented gains, or "baseflows." This at least partially undid the change in model domain, as the baseflows from the ESPA are now assumed to pass through Ralston's "unconnected formations" to reach the Snake River. As will be discussed later, this results in simulation of unrealistic groundwater flow patterns in the Rangen area.

4.4 Model Calibration Process

4.4.1 General Approach

After conceptual formulation and data development, the next step in groundwater model development is calibration. Calibration is a form of "history matching" wherein initial values of model parameters (such as transmissivity) are adjusted to achieve a better correspondence between historical targets (e.g., measured water levels and spring flows) and model-predictions. Ordinary least-squares regression may be the most familiar example of this process; in it, the parameters of the regression equation (slope, intercept) are adjusted to minimize the sum of the squared differences between the regression line and the data observations. In this context, the groundwater model can be viewed conceptually as a regression equation.

Because of the many parameters that must be adjusted (several for each model cell), groundwater model calibration is often done using special software programs that solve this "inverse problem", so called because its aim is to use observed behaviors to specify the model rather than to use the model to describe the behaviors. The software program used to calibrate

[1] In his mapping of the geohydrologic framework of the Eastern Snake River Plain, Whitehead (1992) also excluded the Hagerman Valley from the Quaternary basalt aquifer system.

all versions of ESPAM has been the model-independent Parameter ESTimation program (PEST) developed by John Doherty (Watermark, 2005).

To find the "best" solution to the inverse problem, PEST seeks to minimize an objective function that reflects the overall sum of squared differences (or "residuals") between historical aquifer observations, or "calibration targets", and model predictions. The ultimate goal of calibration is to determine the set of parameter values that produce the smallest overall value of this objective function. Historical calibration targets included observed aquifer water levels, reach gains and spring discharges over the period 1980-2008, though not all targets had continuous data over this period. While PEST produces quantitative measures of calibration success, it is ultimately a matter of judgement for the modeller to decide that a given calibration is "good enough" for the purpose at hand.

The objective function used in model calibration effectively aggregates, using weighting and indexing assumptions, all the residuals in the model calibration data set down to a single number. The weighting assumptions used in ESPAM2.1 calibration were based on judgement. Because the objective function is a single number, it is normal for PEST to identify a parameter set that provides a closer calibration to some targets than to others. As the desired use of the model focuses on ever more detailed locations and time periods, it becomes more and more important to examine calibration success in specific areas of the model.

While the calibration of models with large numbers of parameters (such as ESPAM2.1) allows consideration of more factors affecting aquifer conditions, it increases the risk that any given PEST solution (i.e., an "optimal" set of parameter values) is not unique (Watermark, 2005). This means that there may be many other combinations of parameter values could produce a similarly minimized value of overall model error. This non-uniqueness creates one dimension of overall model uncertainty, which is discussed in more detail in a later section.

4.4.2 Calibration of ESPAM2.1

The parameters that PEST was allowed to adjust in ESPAM2.1 included conventional aquifer parameters such as transmissivity, specific yield, and streambed, drain and GHB conductances. In addition, PEST was allowed to manipulate a number of terms in the aquifer water budget where precise values could not be known. For example, PEST was allowed to adjust tributary inflow estimates and surface water irrigation efficiency assumptions, among other things. Given the large number of active cells in the model and the many aquifer water budget terms considered at each cell, the number of adjustable parameters in ESPAM2.1 calibration is large.

Doherty (Watermark, 2005) cautions that "…increased parameterisation normally results in increased parameter non-uniqueness at the same time as any semblance of model linearity rapidly fades from view." As will be discussed later in this report, the assumption of linearity is fundamental to both IDWR and Rangen efforts to quantify the flow changes resulting from curtailment. The large number of parameters reflected in ESPAM2.1 increases the likelihood that the model is not linear.

Reach gain and spring discharge targets were given greater weight in the calibration of ESPAM2.1 due to the fact that there were a far greater number of calibration target values for aquifer water levels than there were for these discharges. Without preferential weighting, PEST would try to match all targets with similar accuracy, by default placing more emphasis on aquifer water level targets. The weighting applied to targets essentially determines the degree to which PEST "focuses" its effort on minimizing error in certain types of model behavior. PEST provides guidelines for such weighting, but it ultimately becomes a decision made by the modeller.

The ESPAM2.1 was calibrated under the assumption that aquifer transmissivity in any given cell is constant over the calibration period. This assumption is computationally convenient in part because it avoids iterative recalculation of transmissivity as simulated water levels change, but it can lead to overestimation of transmissivity in some areas of the model domain (Johnson, et.al., 2010). A common rule of thumb in determining whether this assumption is justified is that simulated changes in water level should not be greater than 10% of overall saturated thickness (Reilly, et al, 1987). Areas where this condition is most likely not to be met are those where the aquifer is thinnest, such as at its edges, as is the case in the present delivery call. Hinckley (2012) estimates that the saturated thickness of the ESPA in the vicinity of Rangen is on the order of 50 feet. Water level changes in wells near Rangen are on the order of 5 feet, making the assumption of constant transmissivity (and the convenient assumption of linearity that it allows) questionable. Compounding this is the fact that fractures and heterogeneities of a scale much smaller than one mile likely dominate flow hydraulics at the thin edges of the aquifer.

4.5 Calibration Results

Calibration success can be assessed in several ways besides the final objective function value produced by PEST, which is not by itself informative. The most commonly used methods for assessing calibration are visual and mathematical comparisons of simulated values and their corresponding targets. It is also useful to examine simulated and observed flow regimes to assess whether model performance reflects general observations and geological constraints that might not be represented explicitly.

4.5.1 Comparison with Calibration Targets in Rangen Area

Figure 4.6 shows the calibrated and target discharge for the Rangen spring complex from the ESPAM2.1 final calibration, along with other representations of calibration fit. In general, the broader patterns of observed discharge are reflected in the modeled values; multi-year cycles and trends are apparent in both, as are seasonal variations. However, the ESPAM2.1 systematically under-estimates discharge in the early years of the calibration period while over-estimating it in the later years.

This systematic error is more apparent by the analysis of residuals that is also shown in Figure 4.6. This analysis shows the error in monthly simulation relative to mean discharge. If simulation errors are random, this plot of residuals should vary randomly about the zero line over time. In fact, Figure 4.6 shows that that ESPAM2.1 consistently under-predicts (by as much as 15 cfs) the total flows from the Rangen complex in the early part of the calibration period and consistently

over-predicts (by as much as 15 cfs) these flows in the more recent part of the period. Since similar patterns are evident at other target springs in the area it raises the prospect of a more general problem with ESPAM2.1 representation of springs in the Hagerman area and suggests that curtailment analyses, which look forward from present conditions, may over-predict increases in spring discharge from curtailment.

Figure 4.7 shows a comparison between simulated and target water levels in calibration well #989 (7S14E29CDC1). There is no calibration well in the Rangen cell, but well #989 is in the model cell immediately northeast from the Rangen cell and is the closest well used in calibration. The simulated water level in this well is systematically more than 20 feet lower than observed level. Also shown on Figure 4.7 is a comparison between simulated and observed water levels in well 7S14E33BBB1. This well was identified as calibration well #992, but for unknown reasons was not included in the target calibration data set. Figure 4.7 shows that ESPAM2.1 also underpredicts the water level in this well.

In 2008 the IDWR completed a monitoring well (7S14E32SENW, aka the "Rangen Monitor Well") on the plain just above the Curren Tunnel (Farmer, 2009). Observations from this well could not be used in ESPAM2.1 calibration because measurements did not begin until the very end of the model calibration period. Nevertheless, the range of observed values reasonably can be compared to simulated water levels in the Rangen cell for the last few years of the calibration period. This comparison is shown in Figure 4.8. It can be seen that ESPAM2.1 predicts recent water levels in the Rangen cell that are substantially lower than what has been observed in the Rangen Monitor Well.

The underprediction of water levels near Rangen is partly a result of the fact that discharge targets were weighted more heavily than water level targets in the calibration process. If predicted water levels were too low, PEST could still meet the more important discharge target by increasing the drain conductance. This is problematic because it embodies, in the drain conductance parameter, a mischaracterization of the real physical relationship between water levels and flows at Rangen. This, in turn, results in mischaracterization of change in drain flow as a result of simulated change in water level due to curtailment. If the calibrated drain conductance parameter is too high, the benefits to Rangen from curtailment will be over-stated.

That the Rangen discharge calibration is as good as it is despite the underprediction of surrounding water levels illustrates another important modeling concept…that good calibration is not necessarily evidence of correct physical representation (Bredehoeft, 2005).

Table 4.1 lists the ESPAM2.1 drain parameters determined by PEST for target springs in the Billingsley Creek area. Drain elevation assumptions were generally chosen to reflect actual elevations, or a range of actual elevations where multiple drains were used. PEST was allowed to adjust drain conductances as needed to match spring discharge targets using simulated water levels. As can be seen in Table 4.1, the calibrated conductances range over 4 orders of magnitude. This extremely large variation suggests that the set of calibrated parameters is quite fragile and that PEST can readily find alternative parameter sets that provide acceptable calibrations.

4.5.2 Comparison to Observed Conditions in Rangen Area

The ESPAM2.1 posits a strictly linear relationship between water level in the Rangen cell and discharge from the Rangen drain. The ESPAM2.1 drain conductance has a calibrated value of 4.85 cfs/foot, meaning that a one foot increase in water level in the Rangen cell will result in a 4.85 cfs increase in drain discharge. The only water level observations close enough to Rangen to be considered within the Rangen cell are those from the Rangen Monitor Well. Hinckley (2012) demonstrates that Curren Tunnel discharge is not the simple linear function of nearby water level represented in ESPAM2.1, a fact that appears also to be acknowledged by Rangen experts (Brannon, 2009). If this relationship is in fact non-linear, the principle of superposition cannot be used to reliably determine the effects of curtailment on Rangen flows.

Even if a linear relationship were to be derived from Hinckley fig 19, it suggests that a one foot increase in nearby water level would cause a discharge increase of 1.37 cfs rather than the 4.85 cfs embodied in ESPAM2.1. In this case the ESPAM2.1 overstates the benefit from curtailment by nearly a factor of 4.

Observed water level in the Rangen monitor well varies over a range from about elevation 3151 ft to 3166 ft (msl). Farmer (2009) estimated the elevation of the outlet of the Curren Tunnel to be 3145 ft (msl) and the elevation of the lower springs to be about 3100 ft (msl). This suggests that the saturated thickness of the aquifer above the Tunnel outlet is not greater than 6-21 feet and that the saturated thickness of the aquifer above the lower springs is in the range of 50-65 feet. Water levels in the monitor well vary seasonally by about 5 feet, and predicted (by ESPAM2.1) water level change in the Rangen cell from curtailment is about 4 feet. These changes are nearly 100% of the saturated thickness above the Tunnel and about 10% of the thickness above the lower springs, further indicating that the requirements for superposition are not met at Rangen.

Hinckley (2012) has shown that for a given water level in the Rangen Monitor well, the discharge from the Curren Tunnel can vary by 4 cfs. In other words, with *no difference* in observed water level, observed discharge varies by 100% of its average value over the observation period. Similarly, Hinckley has shown that a given level of Rangen discharge can be associated with water levels that vary over a 2.5-foot range. This casts further doubt on the accuracy with which ESPAM2.1 can predict the benefit to Rangen from curtailment.

Figure 4.9 shows the ESPAM2.1 change in calibrated values of aquifer transmissivity in the vicinity of Rangen. Notable on this figure is the fact that transmissivities increase in magnitude closer to the canyon rim above Rangen. This is the opposite of what would be expected as the aquifer thins out and saturated thickness decreases. Some of this is undoubtedly a result of the higher weighting placed on discharge targets than on water level targets, but Johnson (2011) suggests it may be a result of calibration using the assumption of constant transmissivity. It is likely that fracture or conduit flow, more than porous media flow, dominates hydraulic behavior near springs in the rim area. These other flow paradigms are not reflected in any of the MODFLOW constructs used in ESPAM2.1.

Farmer (2009) describes a geological discontinuity in the vicinity of Rangen where the Quaternary basalt forming the main aquifer effectively ends at the canyon rim. The Quaternary basalt below the rim immediately west of Rangen is postulated to have flowed down a "ramp" from the southeast. Because of this discontinuity, groundwater entering this lower basalt flow has to come from the southeast rather than directly through the Rangen area. However, in ESPAM2.1 there is a simulated groundwater flow of 320 cfs across this discontinuity from the Rangen cell into the cell containing Tucker and Stewart Springs. As a result of this high flux, simulated water level in the Tucker/Stewart cell is very high (above actual ground surface) and causes a simulated groundwater gradient sloping to the south. Hinckley (2012) points out that the observed groundwater gradient in this area is in the opposite direction from that simulated by ESPAM2.1. These discrepancies reveal serious model misrepresentation of detailed aquifer behaviour in the Rangen area, and raise doubt as to the accuracy of model predictions there.

4.5.3 Comparison of ESPAM2.1 with Previous Versions of ESPAM

ESPAM1.1 and ESPAM2.0

The IDWR carried out a comparison of ESPAM1.1 and ESPAM2.0 performance (Sukow, 2012a) using the paradigm of the generic curtailment scenarios originally run by IWRRI for ESPAM1.1 (Contor, et al, 2004). This comparison utilized a steady-state version of the primary input file (the .wel file) in both the ESPAM1.1 and ESPAM2.0 and simulated the curtailment to 5 generic dates. Table 4.2 reproduces the results of this comparison for the generic curtailment date of January 1, 1961.

Table 4.2 makes two different comparisons. The first compares results from using the ESPAM1.1 input file in both the ESPAM1.1 and ESPAM2.0; this comparison illuminates the change in model results that can be attributed mainly to changes in model structure and parameters (which have been described above). The second compares results between the two models each using their own input file; this comparison illuminates the change in model results that can be attributed mainly to changes in input data. With respect to spring flows below Milner, the IDWR analysis found that flows due to 1961 curtailment increased from 352 cfs to 454 cfs using the ESPAM2. The analysis also concluded that roughly 75% of this change was the result of changes in model input data, primarily the use of more recent years for estimation of irrigated acreage and irrigation water requirements. This highlights the sensitivity of ESPAM2 results to conditions in particular years. Review of updated comparisons using ESPAM2.1 (Sukow, 2012b) leads to the same conclusion.

ESPAM2.0 and ESPAM2.1

Shortly after its release, an error was discovered in the input data for ESPAM2.0. The error arose in the calculation of the water budget in the Mud Lake area and caused an overestimate of aquifer recharge of approximately 89,000 acre-feet/year in that area of the model domain. The error was corrected and the model was recalibrated creating ESPAM2.1, which was made available on November 16th of this year.

The water budget error at Mud Lake was on the order of 1% of the overall ESPAM water budget. It was expected that the relatively small size of this error and its location at the far northeastern part of the model domain would not result in significant changes to the model at its western end.

Table 4.3 shows the change in calibrated values of drain conductance parameters in the Thousand Springs reach and Rangen area, between ESPAM2.0 and ESPAM2.1. As can be seen in Table 4.3, many of the conductances in the western end of the model domain changed by amounts substantially greater than the 1% change in water budget associated with the correction. The conductance for the Rangen drain decreased by about 4%, but some drain conductances in the area changed by nearly 1000%. Figure 4.9 shows how transmissivity values changed as a result of the error correction. Some cell transmissivities in the area near Rangen changed by as much as 500%. As will be discussed in a later section, these changes in conductance and transmissivity are carried directly into the superposition models used to calculate the flow changes resulting from curtailment. Large changes in calibrated parameter values suggest that ESPAM2.0 and ESPAM2.1 may be over-parameterized, and that other comparable calibration solutions easily can be reached with only minor perturbations in model assumptions. This substantially raises the level of uncertainty in model predictions, since other models can readily be found (by PEST) that are as well-calibrated but have very different parameter values in specific locations.

Further evidence of unexpectedly large changes in ESPAM2.1 is seen in Figure 4.10, which depicts the boundary of the 5% and 10% trimlines for Rangen using ESPAM2.0 and ESPAM2.1. Figure 4.10 shows that the area encompassed by the 5% trimline is substantially larger with ESPAM2.1, but that this expansion is mainly in areas on the opposite side of the Malad Gorge from Rangen. Given the fact that the Gorge severs the Quaternary basalts that form the aquifer (Hinckley, 2012), it is difficult to see why wells west of Bliss should now be viewed as having increased effect on Rangen flows simply because of a small data error at Mud Lake.

4.6 Model Uncertainty

The ESPAM2 is, like all models, a simplified representation of reality, and this leads to model uncertainty. When viewed from a distance, the generalizations and simplifications made to construct the model may be sufficient to support regional scale analyses. However, when called upon to represent highly localized conditions such as those governing discharge from specific outlets of a specific spring complex, the generalizations and simplifications can introduce significant error into model results. Actual subsurface conditions within the ESPA are understood only in specific locations where lithology has been observed (e.g., boreholes and outcrops) and where hydraulic characteristics have been measured (e.g., pump tests). Observations of ESPA geology suggest it is highly complex, comprised of overlapping fractured basalts interspersed with sedimentary formations, with hydraulic characteristics that can vary substantially over short distances (Lindholm, 1996; Hinckley, 2012).

4.6.1 Overview - General Dimensions of Model Uncertainty

Model uncertainty has several dimensions, and these have been described in various submittals to the ESHMC (e.g., Brendecke, 2009a,b; 2012). In a nutshell, the principal dimensions of model uncertainty are those associated with model conceptualization, with model input and with model calibration. While all of these dimensions are important, conceptual uncertainty is fundamental. No amount of data improvement, re-sampling or recalibration can correct errors stemming from incorrect (or simply incomplete) model conceptualization (Bredehoeft, 2005).

Model conceptualization involves the identification and adoption of a model framework that the modeller believes can properly represent the behavior of the underlying real system. At a practical level it is the selection of a modeling code (in the present case MODFLOW) and the formulation of the model structure (e.g., defining the domain, deciding whether to operate it as a confined or unconfined system, adopting cell sizes, layering, boundary conditions, etc.). Previously in this chapter we have examined how many of these conceptual aspects of ESPAM2.1 fail to reflect observed characteristics of the aquifer system in the Rangen area. These failures lead to conceptual uncertainty in the ESPAM2.1.

Rigorous evaluation of conceptual uncertainty is difficult. There may be a large number of plausible conceptual models of an aquifer system and these models can't be rigorously evaluated until they are built. As a result, this critical dimension of model uncertainty is often "swept under the rug" in favor of more constrained and tractable evaluations that focus on input data and calibration. In the case of ESPAM2.1, this conceptual uncertainty bears directly on its suitability in the present matter.

Once a conceptual model has been identified and formulated, it must be populated with input data reflective of the important aspects of the aquifer water budget. In the case of ESPAM2.1, these data include precipitation, tributary underflows, irrigated acreage, crop distributions, surface water supplies, water application methods and efficiencies, etc. Each of these input data types carries its own uncertainties that can stem from, among other things, the inability to measure a condition accurately (or at all) and from the spatial or temporal resolution of measurements. Sometimes these uncertainties can be reduced by further data collection efforts, though these may be time-consuming and expensive. The effects of input data uncertainty can sometimes be explored through sensitivity analysis or through Monte Carlo analysis, which seeks to translate probabilistic descriptions of model input data to probabilistic descriptions of model output.

Once the conceptual model has been populated with input data, it must be calibrated. The calibration process has been addressed previously in this section. Calibration uncertainty essentially reflects the fact that many combinations of model parameter values (which in the case of ESPAM2.1 include aspects of the aquifer water budget) may lead to equally well-calibrated models. The uncertainty arises because the predictions made by these equally well-calibrated models may be significantly different.

4.6.2 IDWR Uncertainty Analysis

The uncertainty of ESPAM2.0, and selected aspects of ESPAM2.1, have been explored by the IDWR using a technique called "Predictive Analysis" that is available as part of the PEST software (Watermark, 2005). Predictive Analysis is described in the PEST documentation as

> "… the task of calculating the effect of parameter uncertainty, as estimated through the calibration process, on predictive uncertainty."

Predictive analysis essentially answers the question "If I use slightly different values for selected model parameters, do I get different values for key model results?" The analysis requires assumptions about the meaning of "slightly different" and whether such differences are small enough that the model can still be considered calibrated. The analysis does not explore alternative conceptual representations of aquifer hydrogeology, although it can be used in a limited way to explore input data uncertainty.

Table 4.3 summarizes the predictive analysis carried out by the Department (Wylie, 2012c,d) for ESPAM2.0, showing updates for selected portions using ESPAM2.1. The analysis made several simplifying assumptions to make the work computationally more efficient; for example, it assumed that pumping stress for entire Water Districts could be applied at the centroid of each District without loss of accuracy. The predictive analysis was designed to be generic, and did not examine parameter sensitivity of predictions of Rangen discharge. The conclusion that can be drawn from Table 4.3 is that parameter uncertainty variable of the model domain (e.g., the relationship between pumping in Water District 34 and reach gains between Blackfoot and Minidoka is apparently larger than that between pumping in Water District 130). The important thing to remember with this analysis is that it relies on a single conceptual model and does not explore the uncertainty that arises from improper conceptualization of local geologic and hydraulic conditions that influence discharge of specific spring complexes, such as those at Rangen.

4.6.3 Rationale for alternative models

In the uncertainty evaluation carried out for the ESPAM2.1, the model and parameter structure are assumed fixed, as are many data inputs. This approach is valuable in illuminating those parameters for which further investigation might reduce the uncertainty of the chosen model (James, et. al., 2009), but does not address larger questions of model uncertainty described above. More exhaustive evaluation approaches, such as Monte Carlo simulation, may shed greater light on the probability distributions of model errors. However, unless such approaches address all the dimensions of model uncertainty, including conceptual uncertainty, they too will be incomplete.

Conceptual uncertainty can only be addressed by considering alternative models. The poor correspondence between ESPAM2.1 assumptions about hydrogeology and aquifer behavior in the Rangen area indicate that at the very least a refined version of ESPAM2.1 is required. One very preliminary set of refinements are discussed in a later section of this report.

4.7 Limitations of ESPAM2

While it is clearly an improvement over its predecessor, several important features are the same in ESPAM1.1 and ESPAM2.1. The two are still conceptually the same regional model. Differences between them are largely the result of differences in input data and in values of calibration parameters resulting from the use of that input data. Both models represent the details of the Rangen spring complex and the surrounding geology in highly simplified form, omitting several key features and that would make significant differences in predicted benefits of curtailment.

Particularly important to the present case is the fact that ESPAM2.1 systematically underestimates water levels in the Rangen area. Because simulated heads are too low in the cells above Rangen, the calibrated drain conductances have to be made higher in order to meet the discharge calibration targets. This means that the drains are overly-sensitive to small changes in head. This over-sensitivity is carried into the superposition model used for curtailment, with the result that changes in spring flows are substantially over-predicted.

For these reasons, the ESPAM2.1 is subject to the same general limitations as ESPAM1.1, despite the increased attention given to the use of springs as calibration targets. That ESPAM2.1 can fairly closely mimic the observed past behavior of a spring complex is not proof that it sufficiently represent hydrogeologic reality to accurately predict future behaviour of that complex, especially under aquifer water use conditions (e.g., curtailment of large amounts of junior groundwater pumping) that are radically different from those extant in the model calibration period.

The ESPAM2.1 documentation describes limitations on model usage, highlighting the facts that a number of simplifying assumptions had to be made and that many components of the model water budget were uncertain. The documentation cautioned that ESPAM2.1 is a regional ground-water model best used for broad-scale predictions.

5.0 SIMULATION OF CURTAILMENT OF JUNIOR GROUNDWATER RIGHTS

5.1 Background

IDWR practice has been to create superposition versions of the ESPA groundwater model for use in evaluating curtailment (and other) scenarios. Superposition models are used primarily for reasons of convenience; it is faster and easier to perform analyses with superposition models than it is with "fully populated" models. A fully populated model contains all the water budget (input) data and parameters used in model calibration; outputs from a fully populated model can reflect simulated values of characteristics that may be directly observable in the aquifer. However, to examine effects of changes in input data, such as reduced pumping withdrawals, it is necessary to make two runs of a fully populated model and then determine effects by differencing the results of the two runs. The use of a superposition model allows this differencing to be accomplished in a single model run.

A superposition model preserves the parameters of the flow relationships between model cells but sets the initial condition of the groundwater flow regime to one of zero flux. Existing fluxes are eliminated by setting all aquifer heads and elevation differences to zero. The aquifer is converted, conceptually, into a still pool but one in which all the water molecules preserve fixed, predetermined relationships to one another. The relationships that are preserved in a superposition model are embodied in the calibrated parameters governing flow rates and responses: transmissivity, specific yield, conductance (of drains, riverbeds, and general head boundaries) and seepage rates from canals. The effect of a selected model stress, such as a reduction in groundwater withdrawal, can then be evaluated with the superposition model simply by applying that incremental stress and examining how heads and fluxes (including reach gains and drain flows) have changed from their zero condition.

The principle of superposition relies on the assumption that the system being modeled behaves in a completely linear way…that is, that flow relationships are independent of flow magnitude. In a linear model, the rate of flow caused by a half-foot difference in water level between two cells will be the same whether the cells contain water 1 ft or 1000 ft deep. Superposition models perform identically at all levels of assumed stress change, even those outside their range of calibration. If the system being simulated exhibits important non-linear behaviors, such as those that have been described in preceding sections of this report, a superposition model can introduce significant error into the analysis of effects of stress changes.

The practice of the IDWR has been to define three superposition versions of the ESPAM, a steady state version (dubbed "SuperSS"), and two transient versions (dubbed "SuperTransient10yr_monthly" and "SuperTransient150yr"). The transient versions allow simulation of how assumed stress changes evolve over time, the former reflecting a repeated seasonal pattern of conditions and the latter reflecting a constant annual pattern. The constant annual pattern is used to assess the speed at which the aquifer reaches equilibrium (steady state) conditions after introduction of a change.

Simulation of curtailment of groundwater irrigation rights junior to Rangen's 1962 Curren Tunnel water right has been carried out with ESPAM2.0 by both the IDWR and by Rangen experts. Simulation of curtailment using ESPAM2.1 has been carried out in a generic sense by the IDWR (Sukow, 2012b) and for the Rangen water rights by AMEC. These simulations are briefly described and evaluated below.

5.2 IDWR Curtailment Analyses

5.2.1 Generic Curtailment Analysis

As part of the development of ESPAM2.1, the IDWR carried out a comparative analysis of the effects of curtailment as simulated by ESPAM1.1, ESPAM2.0 and ESPAM2.1. The simulated curtailments were those described by Contor, et.al. (2005) for ESPAM1.1. The curtailments did not reflect priority dates of any specific water rights nor were they limited spatially to the the Area of Common Groundwater defined in Rule 50 of the Conjunctive Management Rules. The curtailment dates used in the analyses were January 1 of the years 1870, 1949, 1961, 1973 and 1986. The January 1, 1870, curtailment date reflected curtailment of all groundwater use in the model domain except that occurring under tribal water right settlement agreements.

The January 1, 1961, curtailment is roughly comparable to that which would occur under the present delivery call for Rangen's July 13, 1962, water right. Table 4.2 in the preceding section showed the results of the hypothetical 1961 curtailment using ESPAM1.1 and ESPAM2.1.

5.2.2 Rangen Curtailment Analyses

In its document production of June 12, 2012, the IDWR produced model files containing results of curtailment analyses for the present Rangen delivery call. These files indicate that the Department evaluated the effects of July 13, 1962, curtailment with ESPAM2.0 using various "trimline" assumptions.

The "trimline" defines a zone of exclusion outside of which the benefits of curtailing a well are less than a threshold percentage of the amount of water use curtailed, as determined by the groundwater model. The trimline concept was originally adopted by former Director Karl Dreher in his 2005 Orders stemming from the delivery calls of Blue Lakes Trout, Clear Springs Foods, the Surface Water Coalition, Rangen, Inc., and others. Director Dreher adopted a 10% trimline and stated in hearing testimony that he viewed this as a minimum level of model uncertainty, noting that model uncertainty had not been quantified. He went on to say that:

> *"…I made the determination it was not appropriate to curtail such junior priority ground water use if, in fact, we didn't know whether curtailment would result in a meaningful amount of water reaching the calling senior right."* (Transcript at 1167: 4-80)

Table 5.1 summarizes the results of the IDWR curtailment analyses using ESPAM2.0. The analyses considered trimline thresholds between 0.2% and 10%, as well as trimlines limited only by the Rule 50 Area of Common Groundwater Supply and by the ESPAM2.0 model domain. As

the trimline threshold decreases the area encompassed by curtailment increases. As shown in Table 5.1, there are a total of 406 groundwater irrigated acres relying on rights junior to Rangen's 1962 priority within the 10% trimline; there are a total of 565,023 groundwater irrigated acres within the model domain relying on rights junior to Rangen's1962 priority.

Table 5.1 shows that curtailment of the junior groundwater rights within the 10% trimline would immediately eliminate 1,445 acre-feet of groundwater pumping and, at steady state, would cause total modeled flow at the Rangen springs to increase by 0.19 cfs (141 af/y assuming year around flow). This increase in modeled spring discharge represents 9.5% of the pumping foregone by the curtailed wells and, assuming a permitted groundwater diversion rate of 1 miners inch (1") per acre, 0.66% of the curtailed water rights. It would take somewhat less than a year for discharge to reach 90% of this modeled steady state increase.

Curtailment of the junior groundwater rights within the entire model domain would immediately eliminate 1.46 million acre-feet (MAF) of groundwater pumping and, at steady state, would cause modeled discharge from the Rangen spring complex to increase by 18.07 cfs. This increase represents 0.9% of the pumping foregone by the curtailed wells, and 0.06% of the curtailed water rights. It would take approximately 16 years for modeled discharge to reach 90% of this steady state increase.

Foregone groundwater use that is not simulated to accrue to Rangen would accrue to other connected river reaches, springs and baseflows, including those on which there are no water rights or diversions, those on which there are no delivery calls, those on which approved mitigation plans are already in place, and those on which diversions occur under water rights junior to those of the curtailed rights.

5.3 Rangen Analysis

In its December 13, 2011, delivery call Rangen included a curtailment analysis (Exhibit 11 to the petition) carried out by its experts (McGrane et.al., 2011). The details of this analysis were requested at the outset of discovery for this case, but were not produced by Rangen until November 28th of this year. Accordingly, the conclusions below are based primarily on a facial interpretation of Exhibit 11 and may be supplemented when time permits a more careful examination of Rangen's late production.

The Rangen analysis appears to be a transient analysis using average monthly stresses. The use of a transient, average monthly analysis permits the display of simulated seasonal effects of curtailment. It does not appear that the version of ESPAM2.0 used for the analysis is the final calibrated version. The analysis recommends against the use of the trimline concept and concludes with a recommendation that Rangen seek curtailment of all junior (to July 13, 1962) groundwater irrigation rights within the ESPAM2.0 domain. As noted above, this would immediately dry up 565,023 acres of groundwater irrigated land.

Figure 5.1 is reproduced from Exhibit 11 of the Rangen petition. It shows that curtailment would achieve a simulated annual average increase in total Rangen discharge of 17 cfs after 20-plus

years of curtailment. After twenty five (25) years of continuous curtailment, simulated minimum seasonal flows from the Rangen complex would increase by about 9 cfs.

Presumably the curtailed groundwater acreage and water use amounts implicit in the Rangen analysis are similar to those of the IDWR analysis with no trimline, and that similar conclusions could be drawn regarding the portion of curtailed use and water rights that would accrue to Rangen's benefit.

5.4 Rangen Curtailment Using ESPAM2.1

AMEC has carried out analyses of curtailment for Rangen's 1962 water right using ESPAM2.1. These analyses were carried out using the assumption of a 10% trimline. A 10% trimline assumption was adopted based on precedent; previous curtailment analyses and orders by the IDWR have used this assumption, which stems from Director Dreher's Orders in 2005.

AMEC compared the spatial extent of the 5% and 10% trimlines for ESPAM2.1 as defined based on steady-state response functions published by the IDWR (http://www.idwr.idaho.gov/Browse/WaterInfo/ESPAM/model_files/Version_2.1_Current). Figure 4.10 shows the 10% and 5% trimlines for ESPAM2.0 and ESPAM2.1. The 10% trimline is the same for both models, but the 5% trimline for ESPAM2.1 encompasses a larger area than that for ESPAM2.0. This is presumably the result of recalibration due to correction of the Mud Lake data error described previously, though it is difficult to see why a small change in input data in the opposite end of the model domain would cause such a large change in the trimline. It is noteworthy that the extension of the trimline occurs in the area west of Bliss, which is separated from the Rangen area by the Malad Gorge.

Table 5.2 summarizes the steady state results of the 10% trimline curtailment using ESPAM2.1. Curtailment to the 10% trimline has results nearly identical to the ESPAM2.0 analysis done by the IDWR. This curtailment would immediately dry up 406 acres of groundwater irrigated land and eliminate 1,446 acre-feet of groundwater use. Total simulated flow at Rangen would increase 0.21 cfs, which is slightly higher than the 0.19 cfs predicted by the IDWR analysis. This small difference may be attributable to changes in the transmissivity distribution that occurred in recalibration of ESPAM2.1.

6.0 Alternative Conceptual Models

This section describes the development of two alternative conceptual models (labelled #1 and #2 below) of the ESPA in the immediate area of the Rangen complex. The aim of this effort is not to present a definitive reformulation of ESPAM2.1, but to illustrate how a few relatively minor changes to its conceptual structure, suggested by detailed hydro-geologic review, could result in significantly different conclusions from a curtailment analysis. In order for either of these alternative conceptual models to be fully developed, it would be necessary to perform similar analyses at other spring complexes as were presented in the foregoing sections of this report and to extend the reach of calibration from that used herein. Nevertheless, the results of these

preliminary steps at more realistic representation of local hydrogeology illustrate the potential for significant conceptual uncertainty in the application of ESPAM2.1 to localized problems.

6.1 Description of Modifications to ESPAM2.1

The alternative modeling effort focused on making small changes to the construction of ESPAM2.1 to explore what effect these changes have on simulated Rangen discharge and simulated water levels in the vicinity of Rangen. Concepts for these changes are based primarily in hydrogeologic analyses and interpretations presented in Ralston (2008), Farmer (2009) and Hinckley (2012) and on discussions with Neal Farmer on August 22, 2012.

6.1.1 Horizontal Flow Barrier

The main geologic formations that influence the groundwater flow and spring discharge near the Hagerman area are the Quaternary basalts that form the ESPA and the less permeable Tertiary formations (e.g., Glenns Ferry) that underlie it. Current geologic understanding of the Hagerman area is that the ESPA effectively terminates along the Hagerman rim and that the underlying formations restrict subsurface flow from it into the Hagerman Valley. At the south end of the rim, however, Quaternary basalt flows form a "ramp" (Farmer, 2009) creating a pathway to feed lower-elevation springs such as Tucker and Stewart as shown in Figure 6.1. Between this ramp and the rim is a geologic discontinuity, possibly faulting, that restricts groundwater movement directly from the rim to the lower elevation springs. Observed gradients indicate that groundwater flows into this lower area from the southeast rather than the northeast.

To reflect this geological feature, a horizontal flow barrier (Hsieh, 1993) was inserted between columns 12 and 13 for the cells in rows 42 and 43 of the model domain. For model #2, this barrier was shortened to only row 42, as shown in Figure 6.2. A horizontal flow barrier restricts groundwater flow between the cells for which the HFB is defined. With this barrier in place, the preponderance of flow moving southwest through the ESPA must go around the discontinuity to reach the lower springs.

6.1.2 Multiple Drains

Groundwater flows from the Rangen complex emerge at several locations. Farmer (2009) and personal observation note at least two discharge areas, the Curren Tunnel and a set of springs emerging from the slope below it. Farmer estimated the Tunnel to be at elevation 3145 ft (msl) and the lower springs to be at elevation 3100 ft. Koreny (2011) presented spring survey data indicating a Tunnel elevation of 3150 ft "plus or minus two feet." Covington and Weaver (1991) note an elevation of 3138 ft for the "Rangen spring." Elsewhere in the Thousand Springs reach, complexes with discharge points having a range of elevations have been represented using two drains. Given the range and uncertainty in elevations of discharges at Rangen, it seems appropriate to use the same multiple drain construct to represent Rangen as was used in other nearby locations.

Accordingly, another modification made to the alternative models was to represent the Rangen complex using two drains. A new upper drain (DRN218) was added to the Rangen cell, and to the CRIV group. In both models the lower drain was given an elevation of 3100 ft. In alternative model #1 the upper drain was given an elevation of 3152 ft, while in model #2 it was given an elevation of 3148 ft, thus bracketing the upper elevation estimates for the Tunnel presented by Koreny (2011).

6.1.3 Removal of GHB Cells

As noted in Section 4, the use of General Head Boundaries (GHBs) to reflect unmeasured flows from the ESPA to the Snake River effectively undid the removal of the Hagerman Valley from the model domain. Present geologic understanding is that the Hagerman Valley is not part of the ESPA, yet the use of GHBs along the Hagerman rim implies that the ESPA continues through the valley to the river.

It is conceivable that ESPA discharges could be made to the river at the northern and southern edges of the Hagerman Valley. Covington and Weaver note the presence of springs at river level downstream of Lower Salmon Falls dam. Low elevation springs and seeps also exist in the area of the Hagerman Fish Hatchery operated by the State of Idaho.

The third modification made in the alternative models was to remove four GHB cells immediately north of Rangen to prevent simulation of ESPA flows through the Hagerman Valley. This reconfiguration is shown on Figure 6.3. This removal forces baseflows in the Buhl to Lower Salmon Falls reach to move through the remaining GHB cells defined in ESPAM2.1.

6.1.4 Increased Weighting on Recent Rangen Flows

A notable feature of the ESPAM2.1 calibration and validation is the over-prediction of Rangen flows in recent years. Given that any management action would look forward from the present, it seems appropriate that greater emphasis should be placed on simulation of current aquifer behavior. Accordingly, a further modification undertaken in Alternate Model #2 was to assign increased calibration weight to Rangen flow observations after the year 2000. The aim of this modification was to improve the model simulation of Rangen discharge in recent years.

6.2 Calibration of Alternative Models

6.2.1 General Approach

The alternative models were calibrated using the PEST software. Calibration adjustments were limited to parameters in the CRIV group; no recalibration of model transmissivity or specific yield was done, nor were any water budget terms adjusted in the calibration.

Calibration targets for the alternative models were the same as those used in ESPAM2.1, except for the addition of water level targets for PEST well #992. This well, which lies immediately northeast of the Rangen cell, was listed as a target for ESPAM2.1 but was apparently never

used. This inclusion of well #992 added 166 additional target values to the calibration data set. These were given calibration weights the same as those used in ESPAM2.1 for other transient water level targets.

6.2.2 Calibration Results Model #1

Figure 6.4a shows the results of calibration of model #1 for the Rangen discharge and Figure 6.5a shows the results for water levels in wells 989 and 992.

In ESPAM2.1, modeled groundwater levels in calibration well 989 are 20 ft lower than observed levels, and in well 992 the modeled levels are around 2 to 8 ft lower than observed levels (well 992 was apparently not used in the ESPAM2.1 calibration).

In alternative model #1, simulated water levels are higher in both wells, matching observations better than in ESPAM2.1. The most marked improvement is in well 989, which was underpredicted by approximately 20 feet in ESPAM2.1; with model #1 the underprediction is about 10 feet. ESPAM2.1 underpredicted water levels in well 992 by about 5 feet, though somewhat less in more recent years; with model #1 there is good match to water levels in well 992, though there is a slight overprediction in recent years.

The simulated Rangen discharge in model #1 is nearly identical to ESPAM2.1. From the foregoing I would conclude that the calibration of model #1 in the Rangen area is at least as good as that of ESPAM2.1.

6.2.3 Calibration Results Model #2

Figure 6.4b shows the results of calibration of model #1 for the Rangen discharge and Figure 6.5b shows the results for water levels in wells 989 and 992.

In alternative model #2, simulated water levels are not as high as with model #1, but correspondence with well 989 is still improved over ESPAM 2.1. Calibration to flow at Rangen is somewhat poorer in the early years of the calibration than is ESPAM2.1, but calibration in recent years is much better. Model #2 appears to resolve the overprediction problem noted for ESPAM 2 ? in recent years.

6.3 Curtailment Analysis with Alternative Models

Both alternative models were run to simulate curtailment of junior groundwater uses within a 10% trimline. This trimline is consistent with past practice and with IDWR water rights transfer policy. The results of these runs are shown in Table 6.1. Also shown in this table are the results of the same curtailment analysis using ESPAM2.1.

It can be seen by this comparison that the relatively minor modifications made to ESPAM2.1 to better reflect local hydrogeology have substantial effect on simulated benefits to Rangen from curtailment. In the case of alternative model #1, the benefit from curtailment is roughly half that

predicted by ESPAM2.1. In the case of alternative model #2, the benefit is about 5% of that predicted by ESPAM2.1.

6.4 Conclusion

The foregoing alternative model simulations demonstrate how sensitive the predictions from ESPAM2.1 can be to the model representation of local hydro-geologic conditions. Relatively minor changes in ESPAM2.1 conceptualization, made to more closely reflect the local conditions at Rangen, result in model predictions that differ substantially from those of ESPAM2.1. The substantial differences in model predictions highlight the potential magnitude of conceptual uncertainty in ESPAM2.1, a dimension of uncertainty not addressed in the IDWR's predictive analysis.

* SRBA Partial Decree.

** According to a memorandum from Cindy Yenter to Karl Dreher dated December 15, 2003, Rangen's submitted historical flow numbers show that flows have not been available to support water right number 36-7694 since October 1972, which predates the priority year of the right by nearly 5 years. Additionally, during the water right development period flows did not exceed 50 cfs, which is the total of water rights 36-15501 and 36-2551.

INTRODUCTION

The Enhanced Snake Plain Aquifer Model (ESPAM) is an important tool used by the Idaho Department of Water Resources (IDWR) in estimating impacts between ground water use and surface water resources to support water management decisions (Cosgrove and others, 2006). A significant portion of the water that discharges from the aquifer is from springs that are located along the Snake River. The Near Blackfoot to Neeley reach of the Snake River (defined by two stream gauging stations) includes large springs that discharge into the Snake River and the Portneuf River (Figure 1).

The objectives of this report are as follows: 1) describe the hydrogeology in the general vicinity of the Near Blackfoot to Neeley reach of the Snake River, 2) describe how the model represents the hydrogeology of this area and 3) provide recommendations relative to model changes to better represent the field conditions. The report is based on a review of available reports (citations provided in the text), discussions with individuals who work for the IDWR, the University of Idaho (UI) and have worked with the U.S. Geological Survey (USGS) and field site visits in March and October of 2007.

OVERVIEW OF THE AREA

The Near Blackfoot to Neeley reach of the Snake River includes the American Falls Reservoir and is located adjacent to the south margin of the of the Snake River Plain of eastern Idaho. Mundorff (1967, page 7) describes the geologic setting of the area as follows.

> "The Snake River Plain is underlain by a thick sequence of basaltic lava flows, interbedded pyroclastics and sedimentary deposits. The sequence accumulated in a structural trough between much older rocks of the mountain ranges that flank the trough along the northwest and southeast. The total thickness of the fill in the trough is not known, but it is believed, on the basis of geophysical evidence, to exceed 10,000 feet in some places.…
>
> The central part of the plain is generally higher than the margins and contains many lava domes and cones, indicating that at least in the late stages of volcanism, the basalt spread from the central part of the plain towards the northwest and southeast flanks. In the process, the Snake River was crowded against the southeast flank of the plain. Sedimentary interbeds, deposited in stream channels, flood plains and lakes, are thick and extensive along and adjacent to the present course of the Snake River, whereas they are thin or absent toward the central part of the plain."

Mundorff (1967, pages 7-8) provides the following description of the ground-water system.

> "The uppermost few thousand feet of basalt flows, pyroclastics and sedimentary interbeds compose the Snake River Group. These rocks form a great aquifer system – the Snake Plain aquifer – that stores and transmits large amounts of water … Chief sources of recharge to the aquifer are percolation from the channels of the Snake River, Henrys Fork and other streams; percolation from canals and irrigated tracts; and underflow from peripheral valleys and highlands…. The margin of the Snake Plain aquifer is the contact between the

basalt and the consolidated rocks or the sedimentary deposits of lower permeability….The aquifer discharges to the Snake River chiefly in two reaches: between the mouth of the Blackfoot River and American Falls (American Falls Reservoir reach), and between Milner Dam and Bliss (Hagerman Valley reach). Discharge in these two reaches is caused by the specific spatial relationships of the aquifer to aquitards (geologic units of low permeability) in the reach. In the Hagerman Valley reach, the contact between the aquifer and the underlying aquitard intersects the canyon of the Snake River at an altitude generally 100-200 feet above river level, and springs issue at or above that contact. In the American Falls Reservoir reach the contact is generally 20-45 feet above maximum reservoir level."

GEOLOGIC SETTING

Regional Geologic Setting

The Near Blackfoot to Neeley reach of the Snake River including the American Falls Reservoir is underlain mostly by sediments with a large mass of basalt located to the north and northwest. Figure 2 is a geologic map of the area taken from Whitehead (1992) that shows the sediments as alluvium (Qa), wind blown deposits (Qw) and older alluvium (Qts). The basalt shown northwest of the river is identified as younger basalt (Qb) or basalt (Qtb). The general relationship between basalt and sediment is shown on two figures taken from Whitehead (1992). Figure 3 shows the thickness of Quaternary basalt whereas Figure 4 shows the thickness of sedimentary rocks. The two figures show the transition from a basalt-dominated subsurface in the center of the Snake Plain to a sedimentary-dominated subsurface in the vicinity of American Falls Reservoir. In addition, Figure 3 shows that the thickness of Quaternary basalt is greater northeast of the American Falls Reservoir than in the immediate vicinity of the reservoir.

Local Geologic Setting

The local geologic setting includes Tertiary and Quaternary basalt, mostly fine-grained sediments associated with deposition in a lacustrine environment (Raft Formation and American Falls lake beds) and gravel deposits associated with the Snake and Portneuf Rivers. Information on the local geologic setting is provided from four primary papers. Trimble and Carr (1961) describe the geology of the southern portion of the American Falls Reservoir and the surrounding area. Mundorff (1967) provides geologic cross sections and a description of ground water conditions within an area that includes the southern portion of the reservoir. Pierce and Scott (1982) describe alluvial-gravel deposition along the Snake River northeast of the reservoir. Houser (1992) describes the Quaternary stratigraphy of the area northeast of the reservoir and includes a plan map and cross sections.

The geologic history provided by Trimble and Carr (1961) provides an understanding of the relationship of geologic units in the vicinity of the American Falls Reservoir.

"Rocks exposed along the Snake River include rhyolitic and welded tuff of Pliocene age; basalt and basaltic tuff of probable early Pleistocene age; clay silt, sand and gravel of middle to late Pleistocene age, mostly lucustrine and fluvial;

basalt of middle to late Pleistocene age; and alluvium and dune sand of Recent age" (page 1741).

"The oldest rocks prominently exposed in the Snake River canyon are the Pliocene Neeley Lake Beds … and the Walcott Tuff… These two conformable formations crop out mainly along the south side of the Snake River from American Falls southwestward to Rock Creek" (page 1741).

"The next youngest formation… is named the Raft Formation…. The Raft is mainly light-colored poorly bedded to nearly massive silt in the upper part and tan and gray clay, silt and fine sand in the lower part" (page 1742).

"Above the Raft, but possibly intertonguing with it, is a widespread group of nearly contemporaneous basalt flows from several vents northwest of the Snake River. These flows are restricted to the northwest side of the Snake River valley… These basalts are part of what has been mapped as Snake River Basalt… Cedar Butte Basalt..., which is younger than most of the Snake River Basalt, … occurs in an area about 8 or 10 miles long by 4 or 5 miles wide, almost entirely west of the present Snake River Canyon" (page 1742).

"The American Falls Lake Beds, which were deposited immediately after emplacement of the Cedar Butte Basalt, overlie the Snake River Basalt or the Raft Formation … where the basalt is absent… Above the American Falls Lake Beds are deltaic sand and gravel deposits, and several terrace deposits of silt, sand and gravel, all mainly north and east of American Falls" (pages 1742 - 1743).

Mundorff (1967) depicts the subsurface geology of the southwestern portion of the American Falls area, based on information from water wells, in a series of cross-sections that he combined into a fence diagram. A location map and selected portions of the fence diagram are presented in Figures 5a, 5b and 5c. The following points can be drawn from the Mundorff (1967) cross sections.

- The wells in Township 7 South Range 30 East (T7S R30E 29aa1, 20da1 and 20ab1) penetrate a considerable thickness of basalt overlying sediments, shown as the Raft Formation (Figure 5b). The basalt thins considerably to the southeast as is shown by wells 7S 30E 23cc1. The American Falls Lake Beds directly overlie the Raft Formation in this area.
- The basalt penetrated in wells along the northwest side of the reservoir is thinner with basalt flows interlayered with the American Falls Lake Beds and the Raft Formation as shown by well 7S 30E 11aa1 (Figure 5c). Only limited basalt was penetrated by well 6S 31E 32cd1 near the shore of the reservoir.
- Only thin basalt layers are penetrated by wells on the southeast side of American Falls Reservoir (not shown on Figure 5).
- The Mundorff (1967) fence diagram shows that the basalt, which is thick to the northwest in the center of the plain, thins and interfingered with mostly fine-grained sediments (Raft Formation and American Falls Lake Beds) near and likely under at least the southern portion of the reservoir.

Houser (1992) provides the most complete understanding of the subsurface geologic setting of the northeast portion of the American Falls area. Lithologic logs from 240 water wells were analyzed as part of the study and used to prepare a plan map and a number of cross sections. The geologic map prepared by Houser (Figure 6) shows the mapped surface geology and the well locations. The geologic notation used by Houser (1992) is as follows: 1) the American Falls Lake beds is noted as Ql with the Raft Formation as Qr; 2) Pleistocene basalt is noted as Qby or Qb with Snake River Gravel units identified as Qb; and 3) Tertiary basalt is shown as Tb The geologic map (Figure 6) shows the locations of ten cross sections (A-A' through J-J') The geologic cross sections are based on lithologic information from well logs. Selected cross sections are reproduced as Figures 7a, 7b, 7c and 7d. The following points can be drawn from the Houser (1992) map and cross sections.

- The geologic map (Figure 6) shows that the American Falls Lake Beds (Ql) outcrops in a discontinuous pattern over a large area northeast of the reservoir and north of the Snake River.
- The northeast maximum extent of the Raft Formation in the subsurface (subcrop) is shown on Figure 6. This line trends mostly west-northeast across the Fort Hall Bottoms past the town of Springfield. Houser (1992) did not identify the Raft Formation in the subsurface any further to the northeast.
- Geologic cross sections A-A' and B-B' are oriented approximately north-south and extend into the reservoir. The cross sections show that the American Falls Lake Beds (Ql) are present near land surface over much of the area (Figure 7a). The Raft Formation sediments (Qr) underlie the American Fall Lake beds, separated in places by a basalt layer. Either gravel (Qg) or basalt (Qb) underlies the Raft Formation (Qr). The low hydraulic conductivity units, particularly the Raft Formation, are important because they likely limit the hydraulic connection between deeper ground-water flow systems and shallow ground water and the reservoir.
- Cross-sections D-D' and E-E' are oriented northwest-southeast and are located northeast of the reservoir. In cross section D-D' (Figure 7b), the Raft Formation is depicted as extending continuously under the northeast end of the reservoir, the Snake River and the southwest portion of the Fort Hall bottoms. Cross section E-E' shows the Raft Formation as laterally continuous over the area but thinner. Either gravel (Qg) or basalt (Qb) is shown as both underlying and overlying the Raft Formation in sections D-D' and E-E'. The American Falls Lake Beds is a thin, near-surface unit in both of these sections
- Cross sections F-F' and G-G' are parallel to sections D-D' and E-E' but are located up river to the northeast. The American Falls Lake beds are still present as a near-surface unit but the Raft Formation unit is missing (Figure 7c). In section F-F', the Snake River and Fort Hall Bottoms are shown to be underlain by Snake River Gravel deposits (Qg).
- Cross section I-I' trends in a southwest-northeast direction from the northeastern corner of the reservoir to north of Ferry Butte. Cross section J-J' trends from

south-southwest to north-northeast on the east side of Ferry Butte (Figure 6). Cross section I-I' shows that a thick section of the Raft Formation is present under American Falls Reservoir but missing to the northeast (Figure 7d). Houser (1992) shows that a thin clay layer is present between the Quaternary basalt (Qb) and the gravel over about half of the section. Cross section J-J' shows a thinner section of the Raft Formation in the southwest with a considerable thickness of gravel (Qb) overlying Tertiary basalt in much of the area.

- Houser (1992) shows the presence of Tertiary basalt (Tb) under the Snake River Gravel (Qb) at the southwestern (right) end of the four east-west cross sections (D-D', E-E', F-F' and G-G'). The Tertiary basalt is also shown over most of the length of cross section J-J'.
- The Houser (1992) study shows that the fine-grained sedimentary units (American Falls Lake Beds and the Raft Formation) likely are present under the northeast end of the American Falls Reservoir. The Raft Formation is not present in the surbsurface northeast of a line roughly half way between the reservoir and Ferry Butte. The gravel and basalt units likely act as unconfined aquifers northeast of the subcrop line for the Raft Formation and as confined aquifers where they are overlain by the Raft Formation.

Pierce and Scott (1982) provide a description of gravel deposits along the Snake River northeast of the American Falls Reservoir. Their plan view map is reproduced as Figure 8.

> "An extensive gravel deposit of late Pleistocene age, about 15 kilometers wide and at least 10 meters thick, occurs along the Snake River from St. Anthony to American Falls Reservoir (see Figure 8)… Two complimentary effects fostered its accumulation. First, American Falls Lake was dammed by the Cedar Butte Basalt 72,000 +/- 14,000 years ago, resulting in elevated base levels upstream until about 14,000 to 15,000 years ago when the Bonneville Flood drained the lake… Second, conditions that favored deposition in other areas of nonglacial and glacial gravels at this time also existed along the Snake River… Following the drainage of American Falls Lake and the change in stream regimen between late Pleistocene and Holocene time, this gravel fill was incised by the Snake River and its tributaries" (page 695).

The shallow gravel zones shown in the Houser (1992) cross sections near the Snake River and underlying the Fort Hall Bottoms likely are the gravel deposits described by Pierce and Scott (1982). Figure 8 shows that gravel deposits are present northeast of the American Falls Reservoir for a considerable distance beyond Blackfoot.

Summary of Geologic Setting

Four aspects of the geologic setting of the Near Blackfoot to Neely Reach of the Snake River are of particular importance with respect to ground-water flow and the hydraulic interconnection of ground water and surface water.

- The general area of the American Falls Reservoir is underlain by basalt layered with fine-grained sediments. The deposition of fine-grained sediments in this area resulted from damming of the ancestral Snake River by basalt in Quaternary time.

The spatial distribution of the fine-grained sediments, particularly the Raft Formation, provides important control on ground-water flow. The Raft Formation thins generally to the east and northeast and can be identified in the subsurface only to a line approximately half way between the upper end of the reservoir and Ferry Butte. Upward ground-water flow from basalt aquifers into the American Falls Reservoir is likely limited by the presence of the fine-grained sediments of the Raft Formation and the American Falls Lake Beds.

- Gravel associated with the Snake River is present in the subsurface approximately along the present alignment of the river starting above Idaho Falls and continuing down river to thin and terminate against fine-grained sediments near the upper end of the American Falls Reservoir. The fine-grained sediments (Raft Formation and American Falls Lake Beds) in this area effectively block southwestward movement of ground water in the shallow sediments and result in ground-water discharge in the form of springs and river gains, generally northeast of the subcrop of the Raft Formation.
- The presence of the fine-grained sediments at depth in the vicinity of the American Falls Reservoir likely also limits southwestward flow of ground water in the deeper basalt units. This results in upward ground-water flow and discharge of water in the form of springs and river gains.
- The presence of Tertiary basalt at shallow depths in the vicinity of Ferry Butte may also be important relative to controlling ground-water flow. The Tertiary basalt, if less permeable than Quaternary basalt or Quaternary gravel, would be an additional impediment to ground-water flow. Knowledge of the hydraulic properties of the Tertiary basalt is limited.

HYDROGEOLOGIC CONCEPTUAL MODEL

The Quaternary basalt near the center of the Snake Plain generally is considered to host a single, unconfined aquifer. Water producing zones within the Quaternary basalt occur mostly at flow contacts which are present at depth intervals of about 15 to 20 feet. The average hydraulic conductivity of the basalt is extremely high.

The inter-fingering of Quaternary basalt flows with fine-grained sediments in the general vicinity of the American Falls Reservoir likely creates a subsurface environment composed of individual aquifers and confining units (aquitards). The transmissivity of the subsurface in the vicinity of the American Falls Reservoir is postulated to be much lower than the transmissivity of the aquifer to the northwest where fine-grained sediments generally are absent. The hydrogeologic environment in the area northeast of the reservoir is complicated by the presence of a shallow gravel unit roughly parallel to the Snake River. An additional complication is the presence of what is mapped as Tertiary basalt underlying the Quaternary gravel in the vicinity of Ferry Butte. The role that the Tertiary basalt plays in controlling ground-water flow patterns is unknown.

The presence of the fine-grained sediments in the subsurface (Raft Formation and American Falls Lake Beds) likely acts as a restriction for southwestward ground-water flow in both the basalt and the gravel along the Snake River. This results in upward hydraulic gradients and ground-water discharge in the form of springs and river gains.

As noted by previous investigators, most of the ground-water discharge occurs in areas northeast of the reservoir above maximum reservoir level. The sedimentary units likely are present under all but the southwestern end of the American Falls Reservoir. The amount of ground water moving vertically upward through the fine-grained sediments to discharge into the reservoir is believed to be small. The southwestern end of the reservoir is believed to act as a recharge source for ground water. Leakage likely is occurring through basalt that is present in this area.

Two major sources of information are available to combine with the hydrogeologic conceptual model to develop an improved understanding of the ground-water surface water interconnection in the Near Blackfoot to Neeley reach of the Snake River: 1) the locations and temporal variations of ground water discharges (i.e. springs, reach gains) to the river; and 2) the spatial and temporal variations in ground-water levels. Information on ground-water discharges and ground-water levels is described in the following sections.

GROUND-WATER DISCHARGE CHARACTERISTICS

Ground water discharge to the Snake River in the Near Blackfoot to Neeley reach occurs both in the form of identified springs and in the form of river gains that have not been attributed to specific springs. Information on ground-water discharge in the Near Blackfoot to Neeley reach is available from a number of different sources. The following sections provide a summary of information from each specific source.

Stearns and Others (1938)

The springs in the Fort Hall bottoms are described by Stearns and others (1938, pages 137-139) as follows.

> "Springs rise at intervals for a distance of 10 miles or more along the Fort Hall bottoms and adjacent to the Portneuf River near its mouth. Most of these springs rise on the valley floor at heights of 10 to 15 feet above the river. They have a fairly uniform aggregate discharge of about 1,400 second-feet (cfs), and most of them issue from basalt which underlies the alluvium in this area. The flow and the names of 30 of the larger springs in vicinity of the American Falls Reservoir are given below (given in this report in Table 1). The locations of the stations where the flow from these springs were measured are shown in figure … (given in this report as Figure 9)."

> "The ground-water contours … indicate that the springs bordering the Fort Hall bottoms should be divided into two groups. Batise Spring, Fish Hatchery Spring, and Wide Creek, in the Portneuf Valley form one group, and Big Spring Creek, Clear Creek, and Kinney Creek, the waters of which come from the valley of the Snake River north and east of Fort Hall, form the other group."

> "In addition to these springs, 230 second-feet (cfs) of water is discharged by 13 springs in the Aberdeen-Springfield area. These springs issue from the basalt of Gibson Butte, which collects the water from under the irrigated areas to the northeast and from seepage from the Snake River. At most of the spring vents this basalt is overlain by the American Falls lake beds or by alluvium…"

"The Portneuf and Snake Rivers are also augmented by smaller springs and by inflow rising in the stream channels themselves.…. The Snake River between the mouth of the Blackfoot River and American Falls, a distance of about 30 miles, has a total gain, exclusive of surface run-off from the upper Portneuf of about 2,500 second-feet (cfs), nearly all of which is supplied by springs."

Table 1 Spring Discharge Values Reported by Stearns and others (1938)

Number	Name	Discharge		Number	Name	Discharge
1	Rich	18.6		16	Artesian	5.5
2	Johannes	7.2		17	Sterling	6.2
3	Thorn	20.2		18	Colburn	3.2
4	Log Cabin	34.9		19	Ruger	23.9
5	Indian No. 1	47.4		20	Davis	
6	Indian No. 2	21.9		21	Franklin	
7	Indian No. 3	163.5		22	Big Jimmy	37.6
8	Indian No. 4	3.8		23	Big Spring	448.0
9	Indian No. 5	19.3		24	Kinney	29.3
10	Pyle	14.0		25	Clear	130.0
11	McTucker	26.4		26	Ford	7.4
12	Hull	7.1		27	Pocatello City	
13	Tanner	2.2		28	Batise	50.0
14	Crystal	32.8		29	Fish Hatchery	75.0
15	Danielson	51.1		30	Wide	60.0

Stearns and others (1938) discuss the possible sources of inflow to the Snake River in the reach in question. Approximate water balances are prepared for the three identified sources: 1) ground-water flow down the valley of the Portneuf, 2) precipitation on the lava beds north of the Snake River and 3) underflow along the Snake River. Stearns and others (1938, pages 141 and 142) note the following.

"Thus it appears evident that the springs in the Fort Hall bottoms are mainly supplied by this great underflow of the Snake River Valley. Coarse clean gravel deposits and basalt suitable for the accumulation of ground water underlie the river and the irrigated tracts upstream from the springs, but near Blackfoot the gravel deposits grade into relatively impermeable lake-bed silts and clays of the American Falls Basin. As a consequence the ground water that is carried by the gravel deposits tends to be forced into the basalt, which is the only available material of sufficient permeability, and practically all the springs issue from basalt."

Mundorff (1967)

Mundorff (1967) spends a number of pages dealing with a water-budget analysis of the American Falls reservoir reach. He reports the following relative to early flow measurements of the inflow (page 24).

> "Continuous records of flow in the Snake river at the two gaging stations used in the analysis are available only since 1911. Spring inflow at earlier dates can be obtained only by analysis of earlier miscellaneous records. Discharge measurements were made at different places along the Snake River in the vicinity of the American Falls Reservoir reach between 1902 and 1910. By estimating inflow from some tributaries, gains and losses in several reaches, and evapotranspiration losses from the reservoir reach, rough estimates of spring discharge were made for a period in August in three different years. These estimates are 2,000 cfs …in 1902; 1,840 cfs … in 1905 and 1,830 cfs in 1908. Although the records are incomplete and the quantities determined may be considerably in error, the records do indicate that spring inflow in the reach was considerably less before 1908 than in the years since 1911."

Mundorff (1967) presents calculated ground-water inflow to the American Falls reach of the Snake River on an annual basis from 1911 through 1960. The variability in his calculated inflow rates is small with a maximum of 2,055 cfs in 1952 and a minimum of 1,654 in 1916. The range in values from 1940 to 1960 is smaller with a minimum of 1,830 in 1956. Mundorff (1967, page 28) shows that a positive correlation exists between the calculated ground-water inflow to the American Falls reach and the 5-year progressive average of irrigation diversions to the area above American Falls Dam. Mundorff (1967, page 45) states the following in his conclusions.

> "Ground-water inflow in the American Falls Reservoir reach was probably about 1.2-1.4 million acre-feet a year (1,700-1,900 cfs) before irrigation began in eastern Idaho. Inflow increased with the increasing diversions of surface water to land adjoining the Snake River and in the late forties and early fifties averaged about 1.95 million acre-feet annually (2,600 cfs). About 1952 increased withdrawals of ground water apparently became large enough to prevent further increases of ground-water inflow. Between 1922 and 1952 the ground water inflow increased roughly 2.5 acre-feet for every 10 acre-feet of surface water diverted to lands on the Snake River Plain upstream from American Falls Dam."

Mundorff (1967) shows that his calculated monthly ground-water inflow to the American Falls reach correlates reasonably well in the period of 1952 to 1960 with water levels in a shallow well (46-feet deep) located in section 27 of township 5 south and range 31 east. A well driller's report for this well is not available on the IDWR website but other wells in this section penetrate basalt in the depth range of about 20 to about 60 feet.

Balmer and Noble (1979)

Balmer and Noble (1979) present an analysis of the water resources of the Fort Hall Indian Reservation. The study included measurement of water levels in wells and discharge from springs in the Fort Hall Bottoms. The mean flow of major springs on the

Fort Hall Bottoms, as compiled by Balmer and Noble (1979, page 17) is presented in Table 2. Some of the springs identified in Table 2 are the same as included in Table 1 from Stearns and others (1938). It is impossible to know whether flow measurements were taken at the same locations.

Table 2 Discharge of Major Springs on the Fort Hall Bottoms (Balmer and Noble, 1979)

Station	Mean flow in cfs
Hatchery Springs	103
Diggie Creek	263
Jeff Cabin Creek	21.1
Spring Creek	466
Big Jimmy Creek	30.5
Clear Creek	134
Kinney Creek	28.1
Wide Creek	57.4
Jimmy Drinks - East	103
Jimmy Drinks - West	35.4
Ross Fork	58.4

The Balmer and Noble (1979) study includes development of a water budget for the Fort Hall Bottoms. The graphical depictions of their water budget are reproduced as Figures 10A and 10B, a Snake River portion and a Portneuf River portion.

- The Snake River discharge of 4,800 cfs below the Blackfoot River (Near Blackfoot gage) increases to 5,450 cfs where it discharges into the American Falls Reservoir (Figure 10A). About 184 cfs of the total gain of about 650 cfs is noted as “groundwater to channel”. The remaining gain is from identified sources with the largest being Diggie Creek at 263 cfs.
- The Portneuf River flow increased from 270 cfs at the USGS Pocatello gage to 1,744 cfs where it discharges into the American Falls Reservoir (Figure 10B). Specific springs and creeks make up much of the gain. The combined flow of Spring Creek and Jimmie Creek (496 cfs), Clear Creek (134 cfs), Ross Fork (55 cfs), Jimmie Drinks (103 and 35 cfs) plus Wide Creek (57 cfs) is 880 cfs. Unmeasured ground-water inflow makes up an additional 428 cfs.
- Balmer and Noble (1979, page 18) note that the total identified gain to the rivers is about 2,100 cfs. Almost 70 percent of this gain is discharge to the Portneuf River with slightly less than 30 percent of the gain discharging into the Snake River.

Balmer and Noble (1979, page 156) established several temporary gaging stations to quantify inflow to the lower Portneuf River. One station was established at the Michaud Pumping Station near Siphon Road with a second station about one-half mile below Jimmy Drinks East Branch. The approximate locations of these stations are shown on Figure 10B. Six sets of measurements were obtained (dates not given). The river gain was about 619 cfs in this reach with 398 cfs accountable by individual spring inflows. Several measurements near the mouth of the Portneuf River were made during the low water period of 1977 (September 29 and November 1). The measurements indicated river gains of 671 and 637 cfs in the reach below Jimmy Drinks East Branch and the mouth. Discounting the flows in the three measured springs, the unaccounted for gain was 156 and 120 cfs for the two dates.

Kjelstrom (1995)

Kjelstrom (1995, page C17) provides the following summary of information on the gain between the Near Blackfoot and Neeley gages.

> "The Snake River gained about 1.9 million acre-ft of ground-water, largely from springs, between the gaging stations near Blackfoot and Neeley … in water year 1980. Annual streamflow gains in the reach varied little during water years 1912-80… The mean gain from ground water from 1912 to 1980 was 1.8 million acre-ft, or 2,540 ft^3/s; the standard deviation was 80,000 acre-ft, or 110 ft^3/s."

The reservoir was drawn down for dam reconstruction in 1977, providing an opportunity for measurement of the Snake and Portneuf Rivers upstream and downstream from major springs. Kjelstrom (1995, page C18) reports that the total streamflow gain from ground water in the Blackfoot to Neeley reach was estimated to be 2,560 cfs and 2,570 cfs on September 8 and 28, 1977 respectively.

Kjelstrom (1995, page C18) notes that ground-water discharge to the natural channel of the Portneuf River is about 65 percent of the total ground-water discharge to the Blackfoot to Neeley reach. He describes field measurements as follows.

> "Streamflow measurements of the Portneuf River at Pocatello and upstream from Bannock Creek were made on September 9 and 17, 1977. After these measurements adjusted for a measured diversion and estimated surface-water inflow, the average difference between outflow (measured at the downstream gage) and inflow was 1,650 ft^3/s (assumed to be ground-water discharge)".

Kjelstrom (1995), page C21) says that springs issuing from basalt north of the Snake River and American Falls Reservoir discharge about 200 cfs. The largest of these springs is tributary to Danielson Creek. Kjelstrom (1995, page C23) shows that temporal variations in discharge in Danielson Creek correlate well with water-level elevations in well 5S 31E 27aba1 (using data from 1980-81). This is the same well that Mundorff (1967) used to correlate with his calculated ground-water discharge to the American Falls Reservoir reach.

Hortness and Vidmar (2003)

Hortness and Vidmar (2003) present the results of seepage studies that were conducted jointly by the U.S. Geological Survey and the Idaho Power Company for three reaches of the Snake River: 1) lower reach from Minidoka to King Hill, 2) middle reach

from Shelley to Minidoka and 3) upper reach from Ashton to the mouth of the Henrys Fork and Snake River from Heise to Shelley. The seepage studies were conducted in 2001 and 2002. The approach used by Hortness and Vidmar (2003) is described below.

> "Data collected in each reach included discharge values from the USGS and/or IPCo (Idaho Power Company) gaging stations, discharge values at several intermediate locations obtained using acoustic Doppler instrumentation … and measured and/or inspected discharge values for several miscellaneous inflows (mostly tributaries) along the entire length of each reach obtained by field personnel" (page 1).

The Near Blackfoot to Neeley portion of the middle reach of the Snake River was divided into three subreaches using four gaging sites (Figure 11). Station M9 at the upper end of the reach is the USGS stream gaging station entitled Snake River near Blackfoot. Station M12 at the lower end of the reach is the USGS stream gaging station entitled Snake River at Neeley. Acoustic Doppler discharge measurement data were taken at two intermediate stations: M10 – Snake River near Pingree; and M11 – Snake River above McTucker Creek near Pingree. Additionally, measurements or observations were taken at a number of tributaries within the reach. The seepage studies were done twice in 2001 and three times in 2002.

Appendix B of the Hortness and Vidmar (2003) report include tables of discharge data for each of the four stations (discharge readings were not obtained from stations M10 and M11 for all of the seepage runs) plus estimates of selected inflows between the stations and changes in storage in American Falls Reservoir. Table 3 provides a summary of the seepage run results in cfs. Figure 11 shows the seepage run results for the April 9-10, 2002 data collection effort.

Figure 11 show a gain of 460 cfs from station M9 (Near Blackfoot gage) to M11 (head of the reservoir) with a 1,232 cfs gain over the length of the reservoir (station M12 minus station M11). The Hortness and Vidmar (2003) data in Table 3 show a range of stream flow gains of 1,390 to 2,186 cfs from the Near Blackfoot gage (M9) and Neeley gage (M12). The largest calculated gain was in November 2002 with the smallest in July 2002.

The study results shown on Table 3 are different from the results provided in the Hortness and Vidmar (2003) because two errors were discovered in the original document. The first error is in the calculated inflow between stations M11 and M12 for the July 23-24, 2002 seepage run. Two sites are included in estimated inflow for the July 2002 calculations that are not included in analysis of the other four seepage runs. The inflow for the other four seepage runs between stations M11 and M12 is the sum of discharge at the following sites (Hortness and Vidmar 2003, Table B20).

- Portneuf River near Tyhee
- Bannock Creek near Michaud
- Aberdeen Waste Drain near Aberdeen
- Tarter Waster near American Falls
- Seagull Bay near American Falls
- Falls Irrigation Pump near American Falls

Table 3 Summary of Seepage Run Results (cfs) (Hortness and Vidmar, 2003)

Station	April 3-6, 2001	Oct 31-Nov 1, 2001	April 9-10, 2002	July23-24, 2002	Nov 5-6, 2002
M9	2,190	1,810	1,750	3,960	2,060
Est. Inflow	0	0	0	0	0
Est. Outflow	0	0	0	0	0
M10	2,520	2,410			2,430
Est. Inflow	0	0	0	0	0
Est. Outflow	0	0	0	0	0
M11	2,820		2,190		2,550
Est. Inflow	588	481	538	246	421
Est. Outflow	0	0	0	96	0
Res. Storage	800	4,000	2,300	-4,900	4,300
M12	3,920	354	1,660	10,400	367
M10-M9	**330**	**600**			**370**
M11-M10	**300**				**120**
M12-M11	**1,312**		**1,232**		**1,696**
M12-M10	**1,612**	**1,463**			**1,816**
M12-M9	**1,942**	**2,063**	**1,672**	**1,390**	**2,186**

The following two additional sites are included by Hortness and Vidmar (2003) in the calculated inflow between stations M11 and M12 for the July 23-24, 2002 seepage run.

- McTucker Creek Springfield
- Danielson Creek near Springfield

The calculated inflow for the July 23-24, 2002 seepage run is reported in Table B13 of Hortness and Vidmar (2003) is 246 cfs rather than 506 cfs if the two additional stations are not included (see Table 3). Table B13 and Figure B5 in Hortness and Vidmar (2003) show a streamflow gain of 1,131 cfs from the Near Blackfoot gage to the Neeley Gage (M9 to M12). This number is not comparable to the other reach gains presented in the

report because of the inclusion of the two additional sites in the calculated inflow between stations M11 and M12. The corrected calculated gain is 1,390 cfs.

The second error is in the calculated reach gain from M11 to M12 for the November 5-6, 2002 seepage run. As is shown on Table 3, the gain between the Near Blackfoot and the Neeley gaging stations (M9 and M12) was 2,186 cfs. Table B17 and Figure B5 of the Hortness and Vidmar (2003) report show this gain as occurring between M11 and M12 rather than M9 and M12. The correct gain across the American Falls Reservoir (M12-M11) for the November 2002 seepage run is 1,696 cfs.

Hortness and Vidmar (2003) obtained flow measurements at 18 surface water sites that discharge directly into the American Falls Reservoir. Seven of the sites, including the Portneuf River and Bannock Creek, are included in their inflows in the M11 to M12 reach (Table 3). The total discharge of these seven sites ranges from a low of 246 cfs in July 2002 to a high of 588 cfs in April 2001. The eleven remaining surface water sites are: 1) Ross Fork, 2) Clear Creek, 3) Spring Creek, 4) McTucker Creek, 5) Danielson Creek, 6) Sterling Waste, 7) Spring #1 Sterling, 8) Crystal Spring, 9) Spring #2 Sterling, 10) Spring #3 Sterling and 11) Spring Hallow. The combined discharge of these sites was 541.5 cfs in October-November 2001, 634 cfs in July 2002 and 604 cfs in November 2002. Not all of the sites were measured in April 2001 and April 2002. Table 3 shows that the calculated gain across the American Falls Reservoir (M12-M11) was 1,696 cfs in November 2002. Thus, the eleven additional measured inflows to the reservoir (604 cfs) account for about 36 percent of the calculated gain in the American Falls Reservoir reach in November 2002. Most of the remainder of the calculated gain likely is discharge from the spring-fed creeks described by Balmer and Noble (1979) and Kjelstrom (1995) that discharge to the lower Portneuf River. The presence of the sedimentary formations (American Falls Lake Bed and Raft Formation) makes it difficult for large quantities of water to discharge directly into the bottom of the reservoir.

IDWR Reach Gain/Loss Program (2006)

The IDWR Reach Gain/Loss Program is used to develop estimates of historical river gains and losses for various reaches. Cosgrove and others (2006) describe the program as follows.

> "The Reach Gain/Loss Program uses gaged reach inflows and outflows, measured diversions and estimated irrigation returns and reservoir storage and evaporation to calculate a (monthly) water balance for the reach. The residual of the water balance is the estimated river reach gain from or loss to the aquifer" (page 92).

Most of the ground-water discharge to the Snake River occurs in two reaches: 1) Milner to King Hill and 2) Near Blackfoot to Neeley. Cosgrove and others (2006) present calculated average annual river gains in these reaches starting in the early 1900's. A plot of these data is presented in Figure 12. Their description of the temporal pattern of discharge in these two locations is presented below.

> "Natural discharge from the Snake River Plain aquifer is primarily to the Snake River along two reaches: Kimberly to King Hill and Near Blackfoot to Neeley … Spring discharge has varied in response to changes in precipitation, irrigated acreage, and irrigation practices. Overall, discharge in the Kimberly to King Hill

reach appears to have been impacted more than in the Near Blackfoot to Neeley reach…Historically, aquifer water levels and corresponding discharges to the Snake River rose significantly at the onset of surface water irrigation. This is particularly apparent in the historic discharge in the Milner to King Hill reach… Aquifer water levels peaked about 1950 and have been declining since that time. The declines are attributed to the onset of ground-water irrigation, more efficient surface water irrigation practices such as conversion to sprinkler irrigation and canal lining, and the recent seven years of drought. Historic discharge in the Near Blackfoot to Neeley reach shows a less dramatic response to historic changes in irrigation practices, however the reach does exhibit more dramatic seasonal variation since the 1950s" (pages 15-16).

Monthly average river gains, calculated using the IDWR Reach Gain/Loss Program, were obtained from Wylie (2007). The calculated monthly river gains from Near Blackfoot to Neeley results (Figure 13) show a greater data scatter than the annual gains shown on Figure 12. There are some longer-term trends in the river gain with a high in about 1987, a low in about 1995, a high in about 2000 and a low in 2006 that continues into 2007. The average calculated river gain for the reach decreases with time as follows: 2,559 cfs for the period of January 1970 through August 2007, 2,341 cfs for the period of January 2000 through August 2007 and 2,104 cfs for the period of January 2001 through August 2007.

TEMPORAL WATER-LEVEL PATTERNS IN WELLS

The comparison of temporal water-level data from wells from within the basalt-dominated portion of the Snake Plain aquifer to wells near the Near Blackfoot to Neeley reach of the river provides information of hydraulic connection of the ground-water systems. The water-level data were obtained from the U.S. Geological Survey web site.

Hydrographs for selected single completion wells (Figure 14) are presented in Figures 15 through 19. The order of presentation starts with wells completed in basalt north of American Falls Reservoir followed by wells located nearer the reservoir.

- Wells 2N 31E 35dcc1 and 1S 30E 15bca1 (Figure 15) have similar hydrographs and represent the temporal water-level pattern that is typical of the basalt portion of the Snake Plain aquifer northwest of the Near Blackfoot to Neeley reach. Both wells are deep (636 and 751 feet) and the static depth to water is considerably below land surface (594 and 721 feet in 2007). Both wells show a downward overall water-level trend with recent highs in November 1984 and January 1999 and recent lows in August 1981 and August 1994. The water-level rise between August 1981 and November 1984 was about six feet. The seasonal water-level changes in both wells were generally less than two feet with seasonal lows in late spring or summer and seasonal highs in late fall or winter.
- Wells 2S 32E 23bbb1 and 4S 31E 20bbb1 (Figure 16) show a similar water-level pattern as the previous pair of wells. These two wells are 194 and 201 feet deep and have water levels about 171 and 127 feet below land surface. The water-level rise between August 1981 and November 1984 was about five feet in both wells. There is more seasonal scatter in the data points in these wells as compared to wells to the north, probably related to pumping and irrigation application. The

seasonal water-level changes in both wells were generally less than two feet with seasonal lows in spring and seasonal highs in fall.

- Wells 4S 31E 36aba1 and 5S 31E 27aba1 (Figure 17) are both shallow (17 and 51 feet) located in areas irrigated using surface water. The wells show a rapid response to surface water irrigation practices. There is considerable scatter to water-level in both wells with lower water levels in the spring and higher water levels in the fall. The water-level rise from 1981 to 1984, noted in the wells to the north, is not evident in the data from these two shallow wells. The water-level elevation in both wells was lowest in the period of record in 2004-2005.
    - For well 4S 31E 36aba1, the annual water level fluctuation was five to seven feet with no long-term pattern of water-level change from the start of records through the mid 1970's. There is a significant change in the water-level pattern in well 36aba1 starting in about 1978 with lower water level highs and less annual water-level change. Care must be taken to differentiate changes in water-level patterns from apparent changes caused by decreases in frequency of measurement or changes in dates when measurements were taken. The data show a pattern of water-level decline with several multi-year trends (low in 1993 and high in 1999). The water level pattern seen in well 36aba1 is a reflection of change in surface water irrigation practices in the area (such as change from gravity to sprinkler irrigation or lining of canals) and possibly the impacts from ground-water pumping.
    - The overall pattern of the hydrograph for well 5S 31E 27aba1 is similar to well 4S 31E 36aba1 except for larger annual water-level fluctuations. The annual water-level fluctuation was up to 15 feet in the 1950's and 1960's. The range in annual water-level changes lessened (less than nine feet) in the mid 1970's and 1980's with both lower highs and higher lows. Again, some of the change in water-level pattern is from changes in the frequency and/or timing of measurements. An overall downward trend in water levels is evident in the record starting in the early 1980's. The water-level pattern in this shallow well likely is a combination of impacts from changes in surface water irrigation practices and possible impacts from ground-water pumping.
- Well 6S 31E 16bab1 (Figure 18) is located near the northwest shore of American Falls Reservoir. The hydrograph for this 134-foot well has characteristics of the nearby two shallow wells (Figure 17) and the deeper wells to the north (Figures 15 and 16). Seasonal water-level changes were less than about five feet in the 1950's and 1960's, except for scattered low water level readings. According to the USGS record for this well, the pump in the well was operating when the scattered low water-level readings were taken.
- Well 2S 34E 33bba1 (Figure 19) is located near the Aberdeen-Springfield Canal northeast of the American Falls Reservoir. This is 40 feet deep and has high water levels in the fall and low water levels in the spring, which is typical of surface water irrigated areas. The seasonal water-level change generally is five to

six feet. The hydrograph for well 33bba1 is similar to the shallow wells shown on Figure 17. The most likely causes for the water-level pattern in well 33bba1 are changes in surface water irrigation practices in the area and possible impacts from ground-water pumping.

A number of locations have clusters of wells completed to different depths. These wells allow characterization of vertical hydraulic gradients and temporal changes in water-level elevation with depth. Water-level data are available for these wells since about 1980. The locations of the wells are shown on Figure 14.

- Wells 4S 32E 1cba1, 1cba2, 1cba3 and 1cba4 are constructed to depths of 90, 53, 242 and 433 feet respectively and are located near the Aberdeen-Springfield Canal at a site north of the northeast end of the American Falls Reservoir (Figure 14). The water-level patterns for the two shallow wells (Figure 20) are similar with seasonal changes of about 7 to 9 feet and lows in the spring and highs in the fall. The seasonal changes are likely from surface-water irrigation activities. The two deeper wells have much smaller seasonal changes. Figure 20 shows that there was an upward hydraulic gradient between the two deeper completions from the start of the record through about 2002 when the wells had about the same water-level elevation. The scatter in data for the 242-foot well starting in 2005 is difficult to explain. The overall water-level pattern, evident in the three wells with long-term records likely stems from a combination of changes in surface-water irrigation practices in the area and impacts from ground-water pumping.
- Wells 4S 33E 20cbb1, 20cbb2, 20cbb3 and 20cbb4 are located northeast of American Falls Reservoir near the Snake River and are completed at depths of 62, 108, 365 and 738 feet (Figure 14). An upward vertical gradient is evident from the water-level data from all four of these wells (Figure 21). The water-level elevation in the 108-foot well is about 10 feet higher than in the 62-foot deep well. These data indicate an upward vertical gradient of about 0.2 ft/ft. The upward gradient persists deeper in the section but is smaller. The long-term water-level pattern in the 738-foot well is typical of the basalt aquifer to the northwest. This well has one to two feet of seasonal water-level changes with water-level highs generally in early winter and water-level lows in July. This well likely reflects the seasonal impacts of ground-water pumping. The long-term water-level pattern in the 365-foot well is dissimilar from any of the other hydrographs in the area with a high water-level elevation in November 1989 and very small seasonal fluctuations. Reasons for the uniqueness of the hydrograph for the 365-foot well are unknown. The hydrograph for the 108-foot completion has considerable seasonal variation but does not fit the seasonal patterns of other shallow wells in areas of irrigation by surface water. Several significant water level changes (such as 4.5-foot drop between January and March 1992 and a 3.7-foot drop between January and March 1998) are difficult to explain. There are about two-feet of seasonal water-level change in the 62-foot completion well; water-level highs are either in May or September, probably reflecting high river conditions in May and surface-water irrigation impacts in September.
- Wells 4S 33E 25ddb1-2 and 4S 34E 8dbd1-3 are located south of the Snake River and between Ferry Butte and the American Falls Reservoir (Figure 14). Wells

25dbb1 and 25dbb2 have completions at depths of 21 and 117 feet and are located is down gradient (southwest) of wells 8dbd1, 8dbd2 and 8dbd3 which have completions at depths of 38, 99 and 232 feet. Water-level data for these wells are only available during the period of 1985 to 1994 (Figure 22). The water-level data from the 21 and 117-foot completions at 4S 33E 25ddb show an upward vertical gradient of about 0.2 ft/ft with a greater rate of decline during the period of record in the 117-foot completion than in the 21-foot completion. The three completions at 4S 34E 8dbd also show upward ground-water flow but the vertical gradient is smaller (about 0.05 ft/ft). The declining water-level trend in all five of these wells is consistent with this period of record for other wells in the area. The 232-foot completion at 25dbb has a consistent seasonal water-level pattern with low levels in late spring and a high in early winter. A consistent seasonal trend is not as identifiable in the other wells.

- Wells 3S 34E 22dab1 and 22dab2 are located northeast of Ferry Butte and are completed at depths of 85 and 569 feet (Figure 14). Limited water-level data for the 569-foot well are similar in pattern to the 85-foot well with a small downward hydraulic gradient (Figure 23). The overall water-level pattern in both wells is similar to that found in the Snake Plain aquifer to the northwest. The 569-foot well has a seasonal fluctuation of about two to three feet with low water levels in the winter and spring and high water levels in the fall. The 85-foot well has a similar seasonal range in water levels with high water levels generally in the fall.
- Wells 2S 35E 11ddd1-4 are located north-northeast of the City of Blackfoot and are completed at depths of 97, 376, 570 and 682 feet (Figure 14). Note that the scale on the right side of the Figure 24 is for well 11ddd1 (97-foot completion) is three times the range for the other three wells. The hydrograph for the 97-foot well (11ddd1) shows very large seasonal water-level changes (35 to 50 feet), water-level highs and lows that are consistent with surface-water irrigation effects and does not have long-term pattern of water-level decline. There is a downward hydraulic gradient of about 0.18 ft/ft from the 97-foot well to the 376-foot well. The deeper wells at this site have a water-level pattern that is similar to wells located north of American Falls Reservoir with a fairly large seasonal water-level change (three to seven feet). An upward hydraulic gradient was present from the 682-foot completion to the 376-foot completion in the early 1980's. However, these two wells show a downward hydraulic gradient based on the few data points in 2001 and 2002.

Mundorff (1967) notes that shallow wells respond to the large annual range in lake stage only near the southwest end of the American Falls Reservoir. The locations of wells identified by Mundorff (1967) as responding to reservoir stage are shown on Figure 25. A temporal plot of reservoir stage and water-level elevations for one of the wells (7S 30E 24ddc1) for a period of time in the 1960's is presented in Figure 26. The plot shows that the water-level in the well is lower than the surface water at high reservoir stage and higher than the surface water at low reservoir stage. Leakage of water from the west end of the reservoir is likely related to basalt present near land surface in this area.

Geologic Controls for Ground-Water Discharge

Ground water discharges in an area northeast of the American Falls Reservoir because of changes in geology that result in lower aquifer transmissivity in this area. The gravel zone that hosts a shallow ground-water flow system along the Snake River essentially terminates against the fine-grained sediments of the American Falls Lake Beds and the Raft Formation. In the same way, basalt that makes up most of the Snake Plain aquifer occurs only as individual flows within a sequence of mostly fine-grained sediment. The lower transmissivity in the immediate vicinity of the American Falls Reservoir acts similar to a subsurface dam and results in ground-water levels at or above ground surface in shallow aquifers northeast of the reservoir. Springs occur in these areas. There is also a significant upward hydraulic gradient which indicates ground-water flow occurs from deeper aquifers to shallow aquifers and then to discharge locations.

Studies by Balmer and Noble (1979) and Kjelstrom (1995) plus other authors are sufficient to conclude that the vast majority of ground-water discharge occurs upstream of the American Falls Reservoir, probably controlled by the subcrop of the Raft Formation. The amount of ground-water discharge directly into the bottom of the reservoir is unknown but believed to be small.

Estimation of Ground-Water Discharge

The amount of ground-water that discharges to the Snake River in the Near Blackfoot to Neeley reach has been estimated by a number of investigators using a variety of direct measurement and mass balance approaches. The mass balance approach involves measurement of the flow in the river at an upstream site (often the Near Blackfoot site) and subtracting that number from the flow in the river at a downstream site (often below the American Falls Dam at the Neeley site) and adjusting for known inputs and known outputs. Changes in storage within the American Falls Reservoir are also taken into account. The accuracy of the calculated river gain depends on the accuracy of flow measurements and the detail taken in accounting for all inputs and outputs and the change in storage in the reservoir.

The following sections describe the results of the selected investigation efforts.

- Studies conducted by Balmer and Noble (1979) are particularly important because flow measurements were obtained on a large number of springs and tributary streams near the northeast end of the reservoir. Their studies, conducted in the late 1970's, indicate that the Snake River gains about 650 cfs from the Near Blackfoot gage to the reservoir with about 70 percent of the gain from documented sources (individual springs and creeks) and 30 percent from ground-water discharge to the channel. Balmer and Noble (1979) calculated a gain in the Portneuf River from the Pocatello gage to the reservoir of about 1,470 cfs with about 70 percent from documented sources and about 30 percent from ground-water discharge to the channel. This gives a total gain to the rivers of about 2,100 cfs (rounded to two significant digits). Kjelstrom (1995, page C21) says that springs issuing from basalt north of the Snake River and American Falls

Reservoir discharge about 200 cfs. The largest of these springs is tributary to Danielson Creek. Combining the two sources of information, the estimated ground-water discharge to the Snake River in the Near Blackfoot to Neeley reach in the late 1970's was about 2,300 cfs.

- Kjelstrom (1995, page C17) used data from U.S. Geologic Survey stations, measurements of diversions and return flows and changes in reservoir storage to calculate ground-water discharge in the reach using the mass balance approach. He reports the mean gain from ground water between the Near Blackfoot and Neeley from 1912 to 1980 was 2,540 cfs with a standard deviation of 110 ft^3/s.
- The Hortness and Vidmar (2003) seepage run data in a mass balance approach show a range of streamflow gains of 1,390 to 2,186 cfs from the Near Blackfoot gage (M9) and Neeley gage (M12). The largest calculated gain was in November 2002 with the smallest in July 2002.
- The average calculated river gains for the reach for different time periods using the IDWR Reach Gain/Loss Program are as follows: 1) 2,559 cfs for the period of January 1970 through August 2007, 2) 2,341 cfs for the period of January 2000 through August 2007 and 3) 2,104 cfs for the period of January 2001 through August 2007. These values show that the calculated river gains have decreased with time.

Relationship of Ground-Water Levels and Ground-Water Discharge

As with any ground-water system, temporal variations in the discharge from springs in the Near Blackfoot to Neeley reach of the Snake River are related to water-level changes in the source aquifer. Higher discharge from the springs occurs because of higher ground-water levels. The converse is also true. The relationship of ground-water levels to ground-water discharge is described in this section using a well located near Aberdeen and several wells located northeast of the reservoir as compared to calculated ground-water inflow and the discharge of Spring Creek.

Mundorff (1967) compared his calculated monthly values of ground-water inflow to American Falls Reservoir to well 5S 31E 27ab1, located north of Aberdeen (Figure 14). As Mundorff shows (Figure 27), the water-level pattern in the well, which responds to surface irrigation in the area, is similar to the temporal pattern of calculated ground-water inflow to the reservoir.

Water-level data from well 5S 31E 27aba1 (the same well used by Mundorff) are plotted with the monthly reach gains calculated using the IDWR Reach Gain/Loss Program in Figure 28. The seasonal range in water levels in the well was about 15 feet in the 1950's and 1960's and decreased to less than nine in the mid 1970's and 1980's with both lower highs and higher lows. The seasonal range in water levels has been less than seven feet since about 1990. An overall downward trend in water levels is evident in the record starting in the mid 1980's although the frequency of measurement also decreased starting in the late 1980's. Ground-water levels in well 5S 31E 27aba1 show a similar pattern as the calculated reach gain starting about 1990. The drop in water level in the well after about 1998 is very similar to the decrease in the calculated river gain in the same period. The water-level pattern in this shallow well likely is a combination of

impacts from changes in surface water irrigation practices and possible impacts from ground-water pumping. This suggests that the decrease in calculated gains using the IDWR Reach Gain/Loss Program also is a result of the combined impacts of changes in surface water irrigation practices and possible impacts from ground-water pumping.

The analysis of the discharge of Spring Creek with ground-water levels in the area provides an additional opportunity to understand the relationship between ground-water levels and ground-water discharge. Spring Creek heads in a group of springs located west of Ferry Butte and is fed nearly all from ground-water discharge. According to Nathan Jacobson of the U.S. Geological Survey (Jacobson, 2008), the contribution of irrigation return flow to Spring Creek during the irrigation season is a small part (less than 5%) of the total flow. Figure 29 shows the locations of the gaging station on Spring Creek, the springs near Ferry Butte that are the primary source for the stream flow and the locations of nearby observation wells.

The temporal pattern of the discharge of Spring Creek is shown in Figure 30 along with water-level elevations in well 4S 33E 20cbb1. Well 4S 33E 20cbb1 is the shallowest (62 feet) of four wells of various depths that are located about four miles west-northwest of the gaging station location on Spring Creek and about seven miles southwest of the primary springs that feed the stream near Ferry Butte. Daily discharge data are available from the U.S. Geological Survey station Spring Creek at Sheepskin Road starting in the early 1980's. The multi-year temporal changes in the Spring Creek discharge are very similar to the long-term hydrograph for well 20cbb1. There is a high in the mid 1980's, a low in the mid 1990's, a high in the late 1990's and then the lowest discharge and water level in the period of record in 2004-2005. The seasonal features in the two records are harder to correlate, in part because of the different frequency of data points (daily for the creek and every other month for the well). In Figure 30, well 4S 33E 20cbb1 has a seasonal change of about two feet for most of the period of record with highest water levels in the fall. The seasonal water-level pattern in the well appears to change significantly in the period of March 2001 to March 2003 (almost no seasonal water level changes). Reasons for this change are unknown.

The discharge pattern for Spring Creek is compared with hydrographs of two clusters of wells located on the southeast side of the Snake River (the nearest observation wells with temporal records to the gaging station and springs) in Figure 31. Wells 4S 33E 25ddb1 and 25ddb2 are located less than a mile southeast of the Spring Creek gaging station (Figure 29). Both wells are shallow with depths of 117 and 21 feet. Wells 4S 34E 8dbd1, 8dbd2 and 8dbd3 are located south of Ferry Butte and about one mile from the springs that are the primary source of water for Spring Creek. Well depths are 232 feet, 98 feet and 38 feet respectively. Water-level data for these wells are available only from 1985 to 1994. The seasonal change in water levels is small in all five of these wells. The lack of significant seasonal water-level changes fits with the locations of the wells away from irrigated lands and near a ground-water discharge area. The downward water-level trend in the wells is similar to that shown for well 4S 33E 20cbb1 on Figure 30 and correlates with the discharge record from Spring Creek.

The variations in discharge pattern of Spring Creek during on a calendar-year basis over the period of record provide important information relative to ground-water levels and possible causes for changes in both ground-water levels and spring discharge.

Complete year discharge records are available for Spring Creek for the years 1981 through 2007. Figure 32 presents the flow data as average discharge for five-year periods (1981-1985, 1986-1990, 1991-1995, 1996-2000, 2001-2005) and the average of years 2006 and 2007. The entire discharge record for Spring Creek is shown on Figure 30.

- The calendar-year plot of average daily flow of Spring Creek during the period of 1981-1985 (Figure 32) shows a low of 344 cfs on January 1st and July 9th and a high of 414 cfs on October 11th. The discharge steadily increased from the low in July to the high in October with a gradual decrease through the end of the year.
- The average daily flow of Spring Creek during the period of 1986-1990 varied from a low flow of 340 cfs on July 7th to high flows of 390 cfs on May 31st and 387 on October 6th (Figure 32). The flow-rate pattern in 1986-1990 is similar to 1981-1985 except for the lack of a higher peak in the fall.
- The pattern of average daily flows of Spring Creek in 1991-1995 was similar to previous five-year periods only the discharge magnitude was considerably lower. The low flow was 301 cfs on July 9th with high flow rates of 354 cfs on June 6th and 356 cfs on October 7th.
- The 1996-2000 time period includes several years of higher stream flow including the peak flow in the period of record at 605 cfs on June 8, 1998 (Figure 30). The average daily flows of Spring Creek for the 1996-2000 time period (Figure 32) were similar to the 1981-1985 and 1986-1990 periods in shape and magnitude except for the spring high flow period. The average daily high flow value was 419 cfs on June 8th with an average daily low of 337 on July 25th.
- The 2001-2005 time period has much lower average daily discharges than any of the four preceding five-year periods. The average daily high flow was 314 cfs on January 1st with an average daily low flow of 253 cfs on July 3rd.
- The average daily flow of Spring Creek during calendar years 2006 and 2007 are lower than any of the preceding five-year averages with the exception of several short periods. The average daily high flow was 302 cfs on May 5th and October 10th. The average daily low flow was 239 cfs on June 30th.

The average daily discharge plots for Spring Creek, presented in Figure 32, may be used to identify several patterns that are reasonably consistent over the 27 years of record. First, the lowest average daily flow generally occurs in July with a range from June 30th to July 25th. Second, the highest average daily flow mostly occurs either in the spring (May or June) or in October (from 6th to 11th). Third, the July low flow is followed by an October high flow reflects a combination of the impacts of surface water irrigation and the impacts from cessation of ground-water pumping.

Relationship of Surface Water Irrigation and Ground-Water Discharge

Irrigation using both ground water and surface water occurs in the Near Blackfoot to Neeley reach of the Snake River. Figure 33, taken from Cosgrove and others (2006) shows irrigated ground from three sources: 1) ground water, 2) mixed ground water and surface water and 3) surface water.

The Aberdeen-Springfield Canal is the major supply source for surface-water irrigation on the northwest side of the Snake River in the Near-Blackfoot to Neeley reach. As such, the canal diversion records, presented in Figure 34, provide a general temporal view of this water supply source (diversion data obtained from B.A. Contor, 2007). Figure 34 shows an increase in annual diversion per water year from the 1930's into the early 1970's with a peak diversion of about 406,000 acre feet in the 1969 water year. A decrease in diversion rate occurred starting in the 1975 water year with most years less than 350,000 acre-feet per water year. Diversions during the 2000 water year were an exception to the decreasing trend with about 400,000 acre-feet diverted. The diversions during the 2001 through 2005 water years were all less than 300,000 acre feet.

The relationship between annual canal diversions and ground-water levels in a portion of the service area of the Aberdeen-Springfield Canal also is shown on Figure 34. The average annual (taken on a water-year basis) water-level elevations in well 5S 31E 27aba1 are shown along with canal diversions. Water-level data from this well have been presented three times previously in this report: 1) on Figure 17 to represent shallow ground water conditions north of the reservoir; 2) on Figure 27 to show Mundorff's (1967) relationship between calculated river gains and ground-water levels; and 3) on Figure 28 to show the relationship of ground-water levels to river gains calculated using the IDWR Reach Gain-Loss Program. Water-level data from well 5S 31E 27aba1 are presented in Figure 34 as an average over each water year (October 1 through the following September 30). The average values are based on a range in number of data points (weekly measurements in some years ranging to quarterly measurement after 1988). Figure 34 shows that average annual ground-water levels were in the range of 4,380 to 4,383 feet for the period of record up through 1988. With the exception of 1998, all of the average ground-water levels were lower than 4,380 feet. The lowest average ground-water level was 4,375 feet in 2004.

The ground-water levels in well 5S 31E 27aba1 do not immediately follow the decline in diversions in the canal that occurred starting in 1975. The general increase in diversions (with the exception of 1993) that occurred from 1984 to 2000 is also not directly replicated in the ground-water data. There are a number of possible reasons for the differences noted between canal diversion rates and shallow ground-water levels in a portion of the service area. These are: 1) changes in surface water application rates across the service area and in the general vicinity of the well; 2) changes in leakage rates from water delivery systems across the service area and in the general vicinity of the well; and 3) impacts from ground water pumping in the general vicinity of the well. Information is not available at the time of preparation of this report to develop a more detailed cause-effect relationship between canal diversions and ground-water levels in this single well. Sufficient data are available to say with certainty that changes in surface water irrigation practices in the general vicinity of the well 5S 31E 27aba1 have impacted shallow ground-water levels. It is likely that at least a portion of the water-level decline evident in the well hydrograph on Figure 34 is a result of ground-water pumping.

Relationship of Ground-Water Pumping and Ground-Water Discharge

Ground-water pumping from the Snake Plain aquifer is a major portion of the regional water budget. Figure 35, taken from Cosgrove and others (2006), shows that large areas are irrigated using ground water west and north of the Near Blackfoot to

Neeley reach. Other major ground-water pumping centers are located further west, southwest and northeast within the aquifer. The cumulative ground-water irrigation rights on the aquifer, as presented by Contor and others (2006) are presented in Figure 36. This plot shows a dramatic increase in ground-water irrigation rights starting in the 1950's and ending in the 1990's.

The seasonal hydrograph signature for a ground-water pumping area is a water-level high in the spring prior to the starting of pumping and a water-level low in the fall at the end of the pumping season. This is opposite to the signature of a surface-water irrigated area where ground-water levels are low in the spring prior to the start of irrigation and high in the fall at the end of the irrigation season.

None of the observation wells presented and discussed in the report section entitled *"Temporal Water-level Patterns in Wells"* has a seasonal ground-water pumping signature in the water-level record. The presence of the large tracts of land irrigated with surface water between the ground-water pumping areas and the Near Blackfoot to Neeley reach of the river appears to mask out any seasonal water-level changes from pumping wells. However, long-term water level trends such as those shown for wells 2N 31E 35dcc1 and 1S 30E 15bca1 on Figure 15 are detectable in deep wells in the area of interest. Examples are well 4S 33E 20cbb4 which is 738 feet deep (Figure 21) and well 3S 34E 22 dab2 which is 569 feet deep (Figure 23).

Ground-water pumping can impact ground-water discharge in the area northeast of the American Falls Reservoir via the following steps. First, there is a documented upward hydraulic gradient and thus upward ground-water flow from deep zones to shallow zones in the ground-water discharge area. An example of the upward hydraulic gradient is shown on Figure 21. Second, pumping impacts from throughout the aquifer are propagated through the aquifer to the discharge area. Deep wells near the discharge area have hydrographs similar to those near the center of the plain. Third, a decreased upward hydraulic gradient occurs because of greater water-level decline in the deeper zones than in the shallow zones. This is shown on Figure 21 by the comparison of the hydrographs for 4S 33E 20cbb1 at a depth of 62 feet to 20cbb4 at a depth of 738 feet. Fourth, the decreased upward hydraulic gradient results in a reduction in spring discharge.

The magnitude of upward ground-water flow from deep zones to shallow zones and then to discharge areas (such as springs) has not been directly estimated by any of the previous investigators. The magnitude of upward ground-water flow depends on the hydraulic gradient (for which some data are available) and the vertical hydraulic conductivity of the basalt and sediments in the area (for which essentially no data are available). The impacts of ground-water pumping on ground-water discharge also have not been estimated by any of the previous investigators except for model predictions presented in Cosgrove and others (2006).

MODEL REPRESENTATION OF THE HYDROGEOLOGIC SETTING

Characteristics of the ESPAM

ESPAM is a single layer, fixed transmissivity model with 104 rows and 209 columns constructed using the MODFLOW code (Cosgrove and others, 2006). All model cells are 1 mile x 1 mile with a 31.4 degree counter-clockwise rotation relative to east-west. Several types of boundaries were used in the model: 1) no flow, 2) specified flux and 3) head dependent.

The Snake River in the Near Blackfoot to Neeley reach is represented using the River Package. Cosgrove and others (2006) describe the function of river cells as follows.

> "Flow between the aquifer and river or drain cells is governed by equations which are based on Darcy's law (discharge is equal to the product of hydraulic conductivity times cross-sectional area times hydraulic gradient).. In a numerical model, for both river and drain cells, the hydraulic conductivity term represents the conductivity of the river-bed or drain sediments which controls the flow between the river/drain and the aquifer. The gradient … represents the head differential between river stage … and aquifer level" (pages 20-21).
>
> "The flow between the aquifer and a hydraulically connected surface water body is governed by (Darcy's Law)… In the MODFLOW River Package, (Darcy's Law) is implemented in terms of a) stage of the surface water body, b) aquifer water level and c) a conductance term describing the hydraulic conductivity of the riverbed … sediments and the wetted areas of the river bed. The user specifies river stage, elevation of the bottom of the river sediments and conductance of the riverbed sediments. As long as the water level in the aquifer is above the elevation of the bottom of the river sediments, the discharge to (or from) the river is calculated as (discharge is equal to the conductance multiplied by the difference of the river water-level elevation and the aquifer water-level elevation)… (page 30).
>
> "Since riverbed conductance is a lumped parameter (i.e. It represents multiple physical attributes) and impossible to measure, it is commonly estimated during model calibration" (page 32).

The area of the river and reservoir in the Near Blackfoot to Neeley reach is represented using river cells as is shown on Figure 37. Cosgrove and others (2006, Table 3) provide the following information for each of the river cells: 1) row and column (location in the model), 2) stage (for river or reservoir), 3) riverbed conductance in units of square feet per day and 4) riverbed elevation in feet. The stage information was given to represent field conditions. The riverbed elevation was in the range of about 39 to 53 feet lower than stage elevation. The riverbed conductance was held at 99,000 square feet per day for all of the river cells in the reach. As a comparison, the conductance term was set at 157,000 square feet per day for the cells in the Shelley to Near Blackfoot reach and 35,100 square feet per day for the cells in the Neeley to Minidoka reach.

The calibrated transmissivity values for the nodes in the portion of the model near the Near Blackfoot to Neeley reach were obtained from IDWR (Wylie, personal communication, 2008). Figure 38 shows transmissivity values for this portion of the

model in terms of ranges of values. The map shows that high transmissivity values (> 10,000,000 ft^2/day) are included in the model to represent aquifer characteristics north of the east end the American Falls Reservoir.

Calibration of the model was done using automated parameter estimation tools. Cosgrove and others (2006, page 90) describe the process as follows.

> "The goal of model calibration was to adjust model parameters (transmissivity, aquifer storage, riverbed conductance and drain conductance and elevation) until model-predicted values of aquifer water levels and discharges to the river matched observed values. The calibration was done in two steps. An initial steady state calibration was done to establish initial aquifer transmissivity and riverbed and drain conductance. After the initial steady state calibration, a coupled steady state and transient calibration was done. During the coupled steady state and transient calibration, the parameter estimation software would adjust aquifer storage and drain elevation during the transient portion, followed by a check of the steady state model fit. This forced the transient calibration to not only provide a 'best fit' to the transient data but to also honor the steady state observations. Changes to the transmissivity field and riverbed and drain conductance were allowed during the coupled steady state/transient calibration."

Cosgrove and others (2006) show comparisons of model predicted ground water levels as compared to field data. They also show model predicted river gains or losses in comparison to observed or calculated river gains or losses. Model output was compared to ground-water levels in selected wells and to calculated or measured reach gains or losses. The comparison of model predicted gain to calculated gain for the Near Blackfoot to Neeley reach is presented in Figure 39. The model predicted gains are a reasonable representation of the calculated gains over time, although with slightly less variability.

Model Representation of Site Hydrogeology

The Snake Plain aquifer model is of necessity a simplification of a complex ground-water flow system with complex interactions with surface water systems. The primary question is whether changes in the model are needed to make it better represent field conditions. Three topics are presented relative to representation of the Near Blackfoot to Neeley hydrogeology within the model.

- The general construction of the model in the vicinity of the Near Blackfoot to Neeley reach is appropriate for the intended uses of the model. However, construction of a single layer model with one-square mile node spacing does not allow assessment of vertical flow within the aquifer or discharge characteristics of individual springs or stream-gain areas.
- Representation of the Snake River including the American Falls Reservoir using the River Package is appropriate. Hydrogeologic conditions are such that higher riverbed conductance values should be applied to the area between the northeastern end of the reservoir and the Near Blackfoot gage than are applied for the body of the reservoir. The conductance value assigned for the reservoir should be low enough relative to the conductance value for the upper portion of the reach to limit direct discharge into the reservoir to a small value.

- The transmissivity array used in the model does not fit the general hydrogeologic setting of a basalt and gravel dominated system north and northeast of the American Falls Reservoir transitioning into a fine-grained, sedimentary-dominated system under the reservoir. Consideration should be given to making changes in model calibration to achieve a transmissivity array that better fits the hydrogeologic conceptual model. Care must be taken in that the transmissivity values of the single layer model need to represent not just the near-surface sediments and basalt but also the deeper basalt units.
- Consideration of multiple layers for the model should be taken carefully. A multiple layer model can provide an improved representation of areas such as upstream of the American Falls Reservoir where vertical hydraulic gradients are present. However, adding multiple layers increases complexity and thus increased uncertainty in model predictions. Also, data may not be currently available to support the construction and application of a multiple layer model.

CONCLUSIONS AND RECOMMENDATIONS

There is little doubt that ground water discharges to the Snake River in the Near Blackfoot to Neeley reach because the transmissivity in the general vicinity of the American Falls Reservoir is lower than in upstream areas. The gravel zone that hosts a shallow ground-water flow system along the Snake River essentially terminates against the fine-grained sediments of the American Falls Lake Beds and the Raft Formation. In the same way, basalt that makes up most of the Snake Plain aquifer occurs only as individual flows within a sequence of mostly fine-grained sediment. The lower transmissivity in the immediate vicinity of the American Falls Reservoir acts similar to a subsurface dam and results in ground-water levels in shallow and deep aquifers northeast of the reservoir at or above ground surface. The springs occur in these areas. There is a significant upward hydraulic gradient which indicates ground-water flows from deeper aquifers to shallow aquifers and then discharges as springs and stream gains.

The majority of ground-water discharge occurs upstream of the American Falls Reservoir, probably controlled dominantly by the subcrop of the Raft Formation. The amount of ground-water discharge directly into the bottom of the reservoir is unknown but believed to be small.

The ground water that discharges to the Snake River in the Near Blackfoot to Neeley reach is a combination of water from the shallow aquifer in gravel zones along the Snake River and upward flow from deeper aquifers that are hydraulically connected to the basalt system of the main Snake Plain aquifer. The percentage of the discharge that originates from the shallow gravel aquifer likely is higher than the percentage that originates from the deeper aquifer, but the relative amounts are unknown.

As with any ground-water system, temporal variations in the ground-water discharge in the Near Blackfoot to Neeley reach of the Snake River are related to water-level changes in the source aquifer. Higher discharge from the springs occurs because of higher ground-water levels. The converse is also true.

Changes in surface-water irrigation practices in recent years have decreased ground-water levels in shallow aquifers and thus have resulted in reduced ground-water

discharge in the Near Blackfoot to Neeley reach. Ground-water pumping has caused ground-water level declines in the main Snake Plain aquifer and is also a factor in reduced ground-water discharge in the Near Blackfoot to Neeley reach. The well hydrographs and the discharge hydrograph for Spring Creek represent a multiple overlay of impacts from changes in surface water irrigation practices combined with the impacts from ground-water pumping.

The Enhanced Snake Plain Aquifer Model (ESPAM) is a work in progress. Model construction and operation and then modification and improvement are part of a repetitive process that is tied to improved data collection and analysis. Specific recommendations with respect to the model include the following.

- Modify the transmissivity array in the Near Blackfoot to Neeley reach to better represent the subsurface hydrogeologic conditions. The changes should be made with the objective of forcing ground-water discharge from the model to occur primarily in the area between the American Falls Reservoir and Ferry Butte.
- Modify the ground-water conductance such that ground-water discharge occurs upstream from the northeast end of the reservoir and little discharge occurs directly to the American Falls Reservoir. The conductance can be modified to allow leakage from the southwestern end of the reservoir.
- To the extent possible, ground-water discharge to the Portneuf River should be represented in the model.

A revision to the existing water resource data collection network is needed in order to provide an improved basis for understanding the interaction of surface and ground-water systems in the Near Blackfoot to Neeley reach of the Snake River. Suggested improvements to the data collection network are noted below.

- Long-term discharge monitoring stations should be established on one or more additional spring/stream sites upstream from the American Falls Reservoir that have no direct impacts from irrigation return flows or diversions. Data analysis should include comparison to data from the Spring Creek station.
- Routine water-level measurement should be reinitiated on observations wells 4S 33E 25ddb and 4S 34E 8dbd. The measurement program should include either monthly measurements or preferably installation of data loggers.
- Additional collection of water-level data from shallow wells in the immediate vicinity of the Snake and Portneuf Rivers and near major springs is needed to develop a better understanding of ground-water levels and spring discharge and/or river gains.

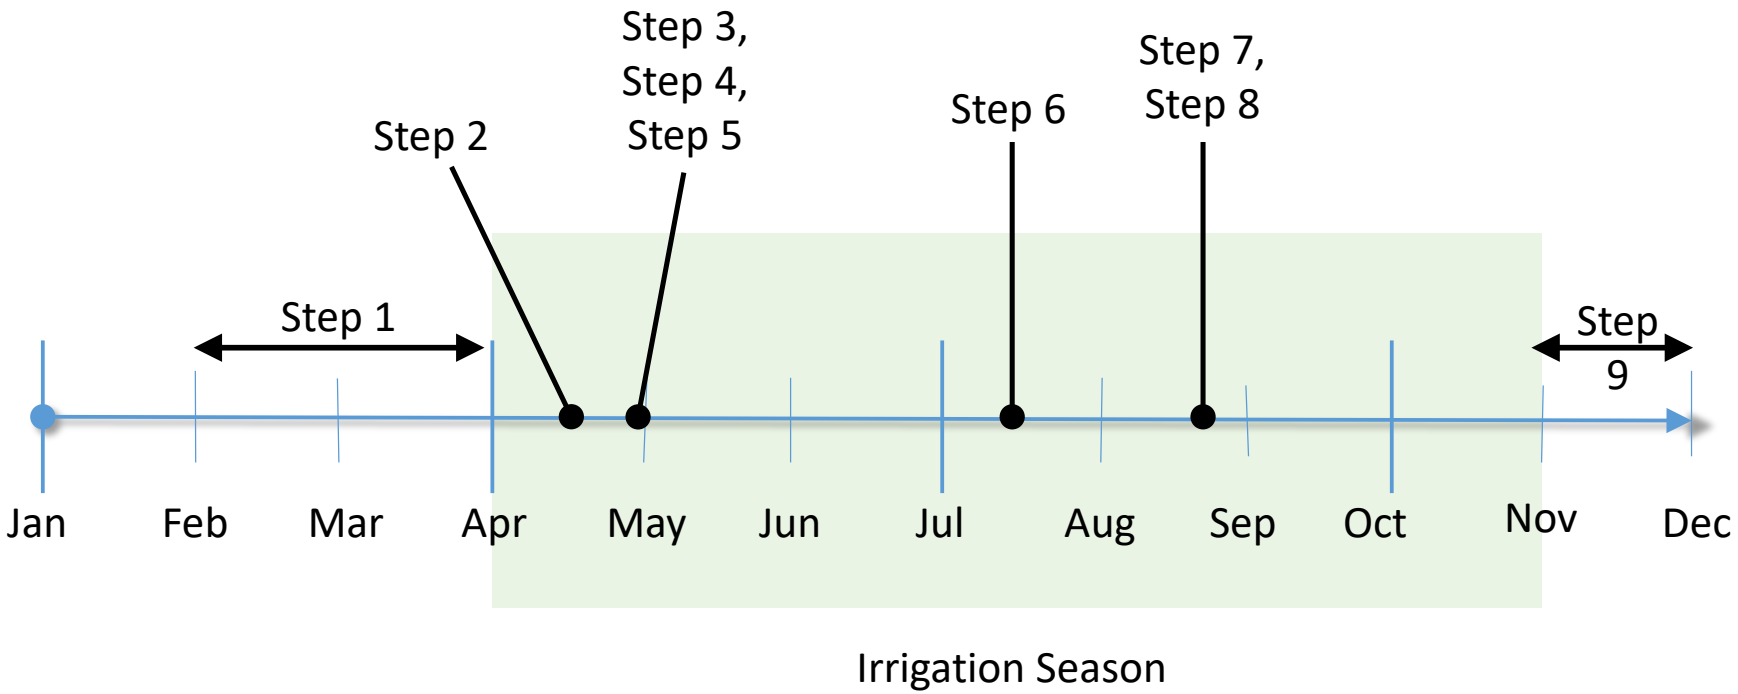
IDAHO Department of Water Resources

IDAHO DEPARTMENT OF WATER RESOURCES

Overview of the Surface Water Coalition Methodology For Determining Material Injury To Reasonable In-Season Demand and Reasonable Carryover

Presented by: Matt Anders & Kara Ferguson

Date: 11/16/2022

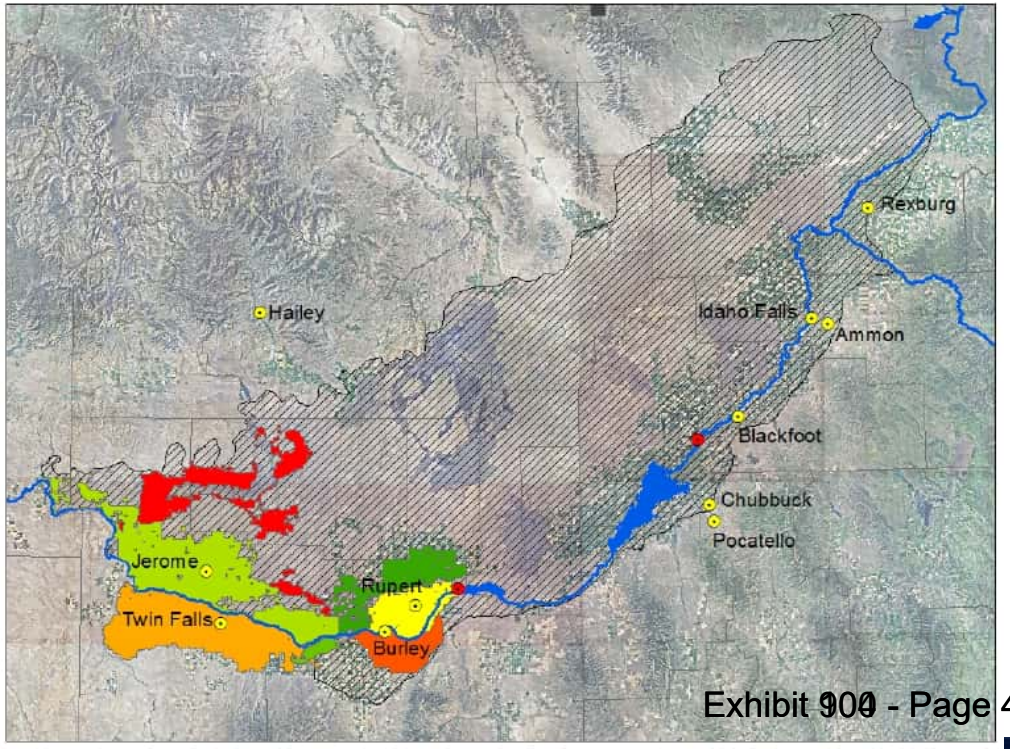


Methodology – Overview

- Delivery Call 1/14/2005
  - Filed under IDAPA 37.03.11 - *Rules for Conjunctive Management of Surface and Ground Water Sources*

- Final Order 9/05/2008
- Second Amended Methodology Order 6/23/2010
- Third Amended Methodology Order 4/16/2015
- Fourth Amended Methodology Order 4/19/2016

- Injury is based on the water supply for the current year
  - In-season injury
  - Reasonable carryover injury
- The water supply changes from year to year…so does the injury obligation



Methodology – Overview

Methodology – Step 1

- By April 1, members of the SWC will submit electronic shape files to the Department delineating the total anticipated irrigated acres for the upcoming year within their water delivery boundary or confirm in writing that the existing electronic shape file submitted by SWC has not varied by more than five percent.

AFRD2	62,361 acres
NSCC	154,067 acres
TFCC	194,732 acres
Minidoka	75,340 acres
A&B	15,924 acres
Burley	46,035 acres
Milner	13,335 acres

Methodology – Step 2

- Completed in April
- Within fourteen (14) days after issuance of the Joint Forecast, the Director will issue a final order predicting the April Forecast Supply for the water year for each SWC entity.
- The Director will compare the April Forecast Supply for each SWC entity to the Baseline Demand for each SWC entity to determine if a demand shortfall is anticipated for the upcoming irrigation season.

Methodology – Step 2

Milestone	Supply	Reasonable In-Season Demand (RISD)
April	Forecast Natural Flow (Apr-Oct) • Regression Equations Predicted Storage Allocation • Analogous year or years	Predicted Demand (Apr-Oct) • Historical Demand from Baseline Year (BLY)

Example - 2021

SWC Member	Forecast Natural Flow Supply	Predicted Storage Allocation	Minidoka Credit Adjustment	Total Supply	RISD (BLY 06/08/12)	Shortfall
A&B	467	122,306		122,773	59,992	0
AFRD2	16,941	364,890	1,000	382,831	427,672	44,800
BID	64,881	213,484	5,130	283,494	251,531	0
Milner	3,050	72,450		75,500	47,135	0
Minidoka	88,905	301,293	8,370	398,568	369,492	0
NSCC	246,664	744,164	(7,750)	983,078	978,888	0
TFCC	741,869	207,120	(6,750)	942,239	1,060,011	117,800
					Total	162,600

Methodology – Steps 3, 4, & 5

- By May 1, or within fourteen (14) days from issuance of the final order predicting the April Forecast Supply, whichever is later in time, junior ground water users with approved mitigation plans for delivery of water must secure, to the satisfaction of the Director, a volume of water equal to their proportionate share of the April Demand Shortfall. The secured water will not be required to be delivered to the injured members of the SWC until the Time of Need.

- Director will issue an order curtailing junior ground water users who:

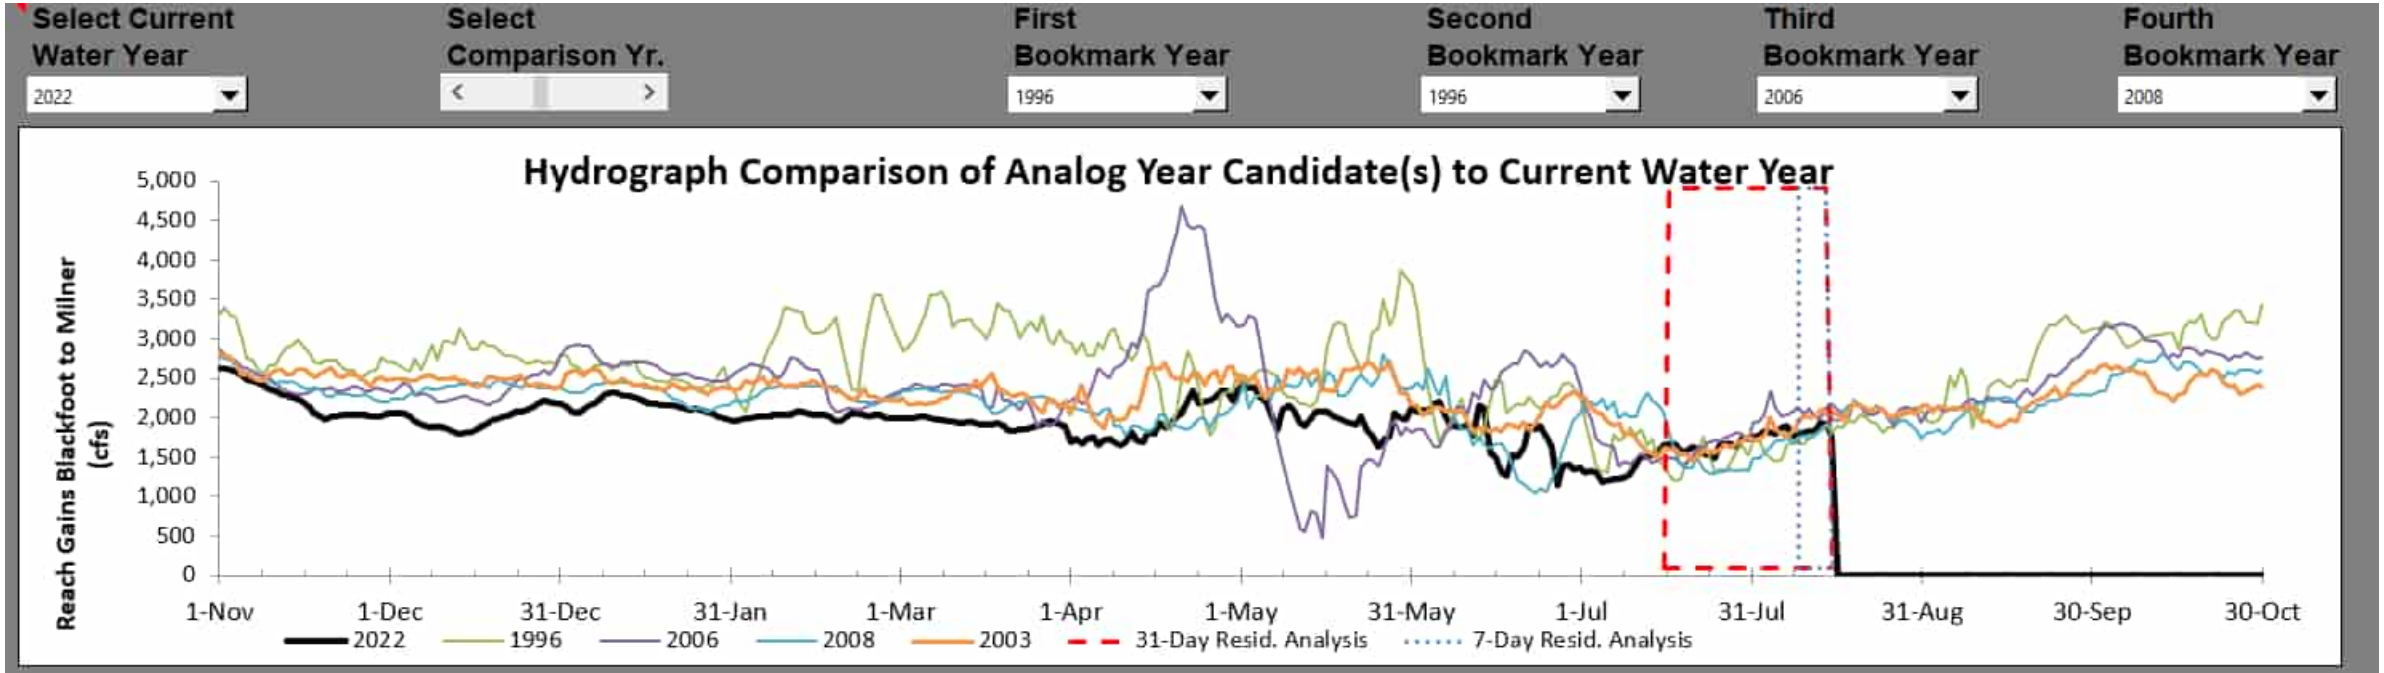
    - (1) do not have approved mitigation plans;
    - (2) fail to secure the required water consistent with their approved mitigation plans; or
    - (3) otherwise fail to comply with their approved mitigation plans.

- If the storage allocations held by members of the SWC do not fill, within fourteen (14) days following the publication of Water District 01's initial storage report, the volume of water secured by junior ground water users to fulfill the reasonable carryover shortfall shall be made available to injured members of the SWC.

Methodology – Step 6

- Completed in July
- Approximately halfway through the irrigation season, but following the events described in Step 5, the Director will, for each member of the SWC:
  - (1) Recalculate RISD;
  - (2) Issue a revised Forecast Supply, and
  - (3) Estimate the Time of Need date.

Methodology – Step 6



Milestone	Supply	Reasonable In-Season Demand (RISD)
July	Actual Diverted Natural Flow (Apr-June) Forecast Natural Flow (July-Oct) • Regression Equations Storage Allocation • Storage Report or Analogous Year	Crop Water Need (Apr-June) • ET • Precipitation • Project Efficiency Predicted Demand (July-Oct) • Historical Demand from Baseline Year (BLY)

Example - 2021

SWC Member	Actual Diverted Natural Flow (Apr-June)	Forecast Natural Flow (July-Oct)	Natural Flow Adjustment	Preliminary Storage Allocation	Minidoka Credit Adjustment	Total Supply	RISD	Shortfall
A&B	12	0	0	106,072	0	106,084	59,008	0
AFRD2	40,438	0	(2,425)	338,244	1,000	377,257	423,430	46,200
BID	85,459	11,633	(3,800)	202,292	5,130	300,715	233,921	0
Milner	9,464	123	(2,900)	63,046	0	69,733	50,585	0
Minidoka	93,175	15,515	0	251,631	8,370	368,691	349,372	0
NSCC	287,666	94,427	0	762,788	(7,750)	1,137,131	961,652	0
TFCC	367,078	449,532	(139)	220,394	(6,750)	1,030,115	1,036,539	400
							Total	52,600

Methodology – Step 6

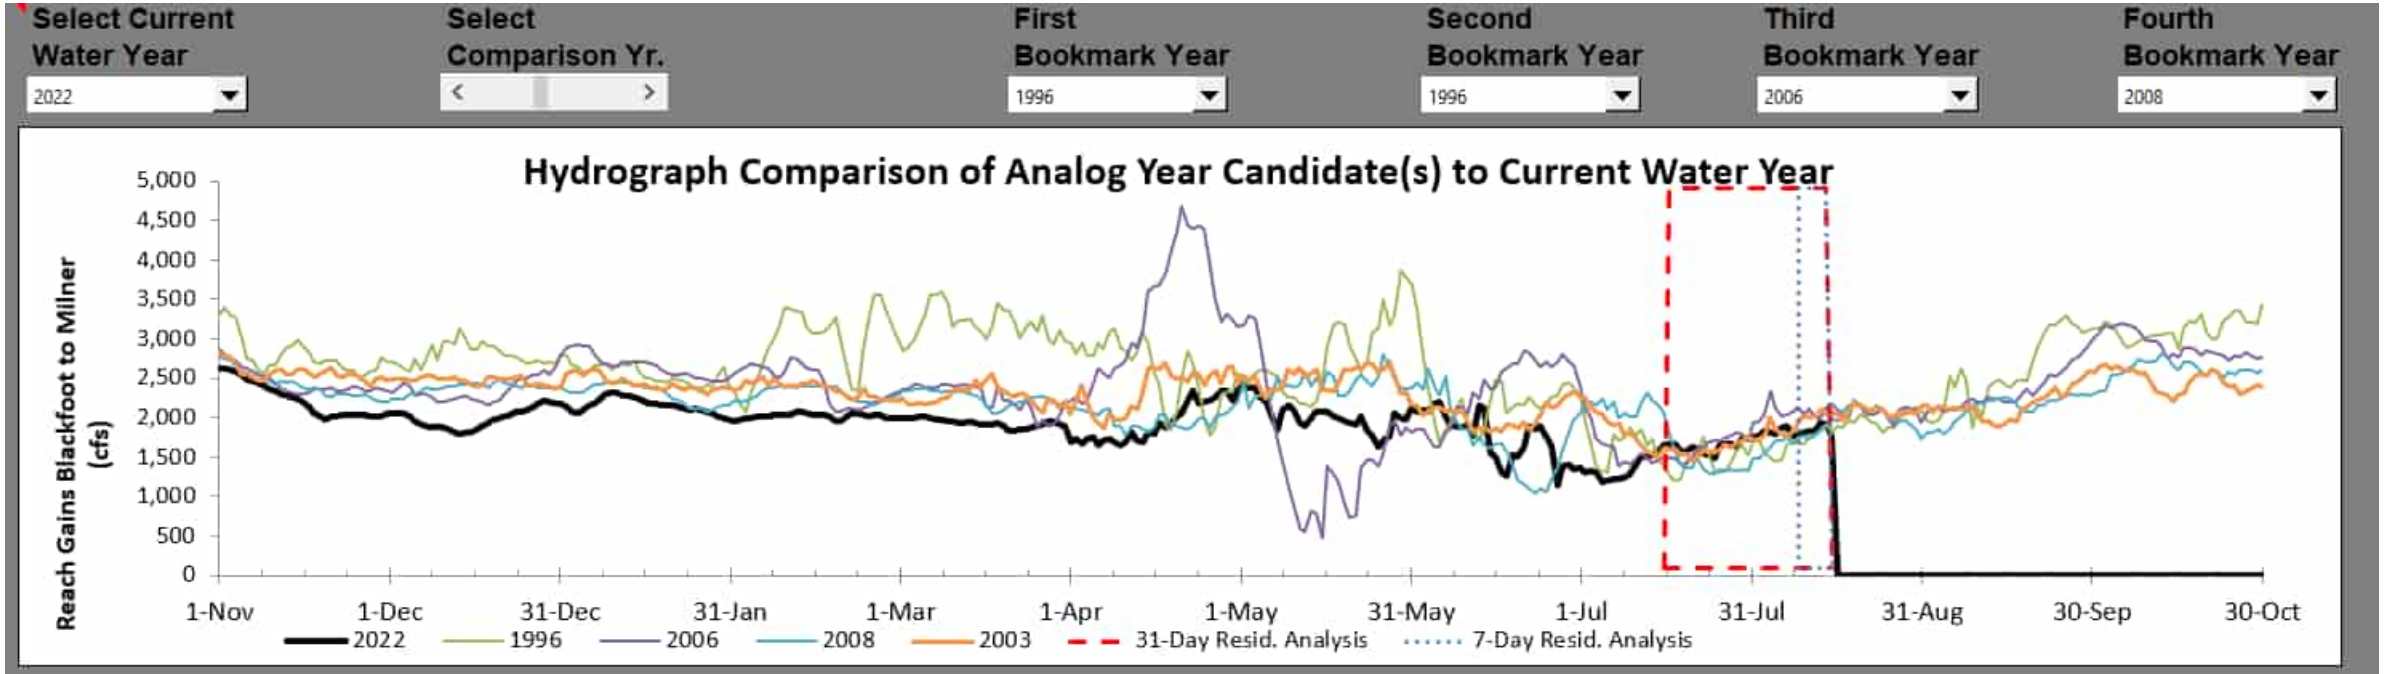
- Estimate the Time of Need date.

Avg. % Resid.	CY: 2003	BM1: 1996	BM2: 1996	BM3: 2006	BM4: 2008
Entire Water Yr.	-18.6%	-32.3%	-32.3%	-20.3%	-11.8%
31 Day Detail	-1.6%	9.6%	9.6%	-6.7%	8.6%
7 Day Detail	-10.3%	3.3%	3.3%	-13.4%	0.6%

Methodology – Step 7

- Completed before the Time of Need (~August)
- Shortly before the estimated Time of Need, but following the events described in Steps 5 and 6, the Director will, for each member of the SWC:
  - (1) Recalculate RISD;
  - (2) Issue a revised FS; and
  - (3) Establish the Time of Need.

Methodology – Step 7



Milestone	Supply	Reasonable In-Season Demand (RISD)
Time of Need	Actual Diverted Natural Flow (Apr-Time of Need) Forecast Natural Flow (Time of Need-Oct) • Natural Flow from Comparable Year Storage Allocation • Storage Report	Crop Water Need (Apr-Time of Need) • ET • Precipitation • Project Efficiency Predicted Demand (Time of Need-Oct) • Historical Demand from Baseline Year (BLY)

Example - 2021

SWC Member	Actual Diverted Natural Flow (4/1 to 8/15)	Forecast Natural Flow (8/16 to 10/31)	Natural Flow Adjustment	Preliminary Storage Allocation	Minidoka Credit Adjustment	Total Supply	RISD	Shortfall
A&B	0	0	0	106,072	0	106,072	58,495	0
AFRD2	40,611	0	(2,425)	338,245	1,000	377,431	435,494	58,100
BID	97,654	1,521	(3,714)	202,293	5,130	302,884	234,407	0
Milner	9,705	0	(3,011)	63,046	0	69,740	55,691	0
Minidoka	93,765	1,555	0	251,632	8,370	355,323	341,626	0
NSCC	312,089	33,294	0	762,791	(7,750)	1,100,423	991,743	0
TFCC	529,573	252,324	(139)	220,395	(6,750)	995,403	1,069,430	74,000
							Total	132,100

Methodology – Step 7

- Establish the Time of Need date.

Avg. % Resid.	CY: 2003	BM1: 1996	BM2: 1996	BM3: 2006	BM4: 2008
Entire Water Yr.	-18.6%	-32.3%	-32.3%	-20.3%	-11.8%
31 Day Detail	-1.6%	9.6%	9.6%	-6.7%	8.6%
7 Day Detail	-10.3%	3.3%	3.3%	-13.4%	0.6%

Exhibit 900 - Page 13

Methodology – Step 8

- At the Time of Need, junior ground water users are required to deliver to each injured member of the SWC the Step 7 revised Demand Shortfall calculated at the Time of Need.

Methodology – Step 9

- Completed in November
- Following the end of the irrigation season (on or before November 30), the Department will determine the total actual volumetric demand and total actual CWN for the entire irrigation season.
- On or before November 30, the Department will issue estimates of actual carryover and reasonable carryover shortfall volumes for all members of SWC.

Methodology – Step 9 Demand Shortfall

Milestone	Supply	Reasonable In-Season Demand (RISD)
November	Actual Diverted Natural Flow (Apr-Oct) Storage Allocation • Storage Report	Crop Water Need (Apr-Oct) • ET • Precipitation • Project Efficiency

Example - 2021

SWC Member	Actual Diverted Natural Flow (Apr-Oct)	Natural Flow Adjustments	Preliminary Storage Allocation	Storage Adjustments	Total Supply	RISD (Apr-Oct)	Demand Shortfall
A&B	2,879		132,913		135,792	67,666	0
AFRD2	64,375	7,101	382,492	1,000	454,968	486,878	31,900
BID	102,479	3,700	220,123	5,130	331,432	273,584	0
Milner	11,134	3,000	83,050		97,184	64,834	0
Minidoka	133,539		314,318	8,370	456,226	415,254	0
NSCC	344,787	0	834,679	(7750)	1,171,716	1,100,537	0
TFCC	831,340	1,095	237,962	(6750)	1,063,647	1,277,798	214,200
							246,100

Methodology – Step 9 Carryover Shortfall

Milestone	Carryover
November	• Actual Carryover • Reasonable Carryover

Example - 2021

SWC Member	October 31 Carryover in Water Rights Accounting	Storage Received for Mitigation	Storage Water Private Leases or to Rental Pool	Carryover Adjusted for Water Provided from SWC for Mitigation(-) or Leased (+)	Reasonable Carryover	Reasonable Carryover Shortfall
A&B	74,265	7,488	0	66,777	18,500	0
AFRD2	2,690	7,733	5	(5,038)	11,500	16,538
BID	55,709	4,388	699	52,020	0	0
Milner	27,713	1,170	4,000	30,543	4,800	0
Minidoka	72,652	0	36,000	108,652	0	0
NSCC	126,682	11,602	0	115,080	65,500	0
TFCC	8,707	31,615	0	(22,908)	25,200	48,108
						64,647

Evaluation of Method for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover: April and July Forecast Supply

Presented by: Kara Ferguson

Date: 11/17/2022

Elements of Shortfall Calculation – Forecast Supply

Milestone	Supply	Reasonable In-Season Demand (RISD)
April	Forecast Natural Flow (Apr-Oct) • Regression Equations Predicted Storage Allocation • Analogous Year or Years	Predicted Demand (Apr-Oct) • Historical Demand from Baseline Year (BLY)
July	Actual Diverted Natural Flow (Apr-June) Forecast Natural Flow (July-Oct) • Regression Equations Storage Allocation • Storage Report or Analogous Year	Crop Water Need (Apr-June) • ET • Precipitation • Project Efficiency Predicted Demand (July-Oct) • Historical Demand from Baseline Year (BLY)

Elements of Shortfall Calculation – Forecast Supply

Milestone	Supply	Reasonable In-Season Demand (RISD)
Time of Need	Actual Diverted Natural Flow (Apr-Time of Need) Forecast Natural Flow (Time of Need-Oct) • Natural Flow from Comparable Year Storage Allocation • Storage Report	Crop Water Need (Apr-Time of Need) • ET • Precipitation • Project Efficiency Predicted Demand (Time of Need-Oct) • Historical Demand from Baseline Year (BLY)
November	Actual Diverted Natural Flow (Apr-Oct) Storage Allocation • Storage Report	Crop Water Need (Apr-Oct) • ET • Precipitation • Project Efficiency

Methodology Reference

- April Forecast Supply (pages 17 & 18 of Methodology)
  - *The forecast supply is comprised of natural flow and stored water.*
  - *With data from 1990 through the irrigation year previous to the current year, a regression equation will be developed for each SWC member.*
  - *The regression equations for **A&B and Milner** were developed by comparing the actual Heise natural flow to the natural flow diverted.*
  - *For **AFRD2, BID, Minidoka, NSCC, and TFCC**, multi-linear regression equations were developed by comparing the actual Snake River near Heise natural flow and the flows at Box Canyon to the natural flow diverted.*
  - *The regression equations will be used to predict the natural flow diverted for the upcoming irrigation season.*
  - *The actual natural flow volume predicted will be one standard error below the regression line, which underestimates the available supply.*

Forecast Supply – Developing Regression Equations

- *With data from 1990 through the irrigation year previous to the current year, a regression equation will be developed for each SWC member.*

- Linear Regression Models
  - Input
    - Historic April-October natural flow diverted
    - Historic predictor variable data (e.g., Heise discharge, Box Canyon discharge, depth to well, SWE)
  - Output
    - Regression equation components:
      - Predictor variable coefficients
      - Intercept

response / dependent variable = predictor variable coefficient (predictor variable) + intercept

    - Regression statistics:
      - R-squared, adjusted R-squared, correlation coefficient, standard error, # of observations

Evaluating Regression Model Performance

- R-squared (coefficient of determination)
  - The proportion of variance in the response variable that can be explained by the predictor variable(s) in the model.
  - The R-squared value ranges from 0 and 1.
    - 0 indicates that the predictor variable(s) explains NONE of the variability of the response variable.
    - 1 indicates that the predictor variable(s) explains ALL of the variability of the response variable.
  - Adjusted R-squared is a modified version that adjusts for the number of predictors in the model.

Forecast Supply – Developing Regression Equations Outliers

- In regression analysis, an outlier is an observation for which the residual (actual – predicted) is large in magnitude compared to other observations in the dataset.
- Removal of outliers from the dataset used to develop the model may improve model performance.
- Identifying outliers
  - Used since 2016 – years with absolute value of residual greater than two times the residual standard error removed from model development.

Year	Actual Natural Flow	Predicted Natural Flow	Residual (actual - predicted)
1990	974,792	918,339	56,454
1991	956,689	943,827	12,863
1992	772,034	842,889	-70,855
1993	929,167	906,909	22,258
1994	832,820	823,586	9,235

*Regression models built using irrigation year (Nov-Oct) natural flow diversion totals.

Methodology Reference

- July Forecast Supply (pages 17 & 18 of Methodology)
  - *The Department's WRA program will compute year-to-date natural flow diverted by each member of the SWC. The natural flow diversion for the remainder of the irrigation season will be estimated based on the regression analyses.*
  - *The regression equations for **AFRD2, A&B, and Milner**, were developed by comparing July 1 snow water equivalent at the Two Oceans Plateau SNOTEL site to the natural flow diversions. The regression equations would be applied only in those years when the SWE is greater than zero.*
  - *Multiple linear regression equations for **BID, Minidoka, and NSCC** were developed to predict natural flow diversions employing the following predictor variables: (1) Snake River near Heise natural flow (April-June), (2) March depth to water at well 05S31E27ABA1 and (3) the SWE at the Two Oceans Plateau SNOTEL site on June 15.*
  - *The multiple linear regression model for the **TFCC** will be based on the following predictor variables: (1) Snake River near Heise natural flow (April-June), (2) Spring Creek total discharge (January – May) and (3) the SWE at the Two Oceans Plateau SNOTEL site on June 15.*

July Forecast Supply – Forecasting Natural Flow

- *The regression equations for **AFRD2, A&B, and Milner**, were developed by comparing July 1 snow water equivalent at the Two Oceans Plateau SNOTEL site to the natural flow diversions. The regression equations would be applied only in those years when the SWE is greater than zero.*

predicted natural flow diverted = Two Ocean coefficient (**7/1 SWE Two Ocean SNOTEL**) + intercept

Current Method - USDA Crop Data Layer

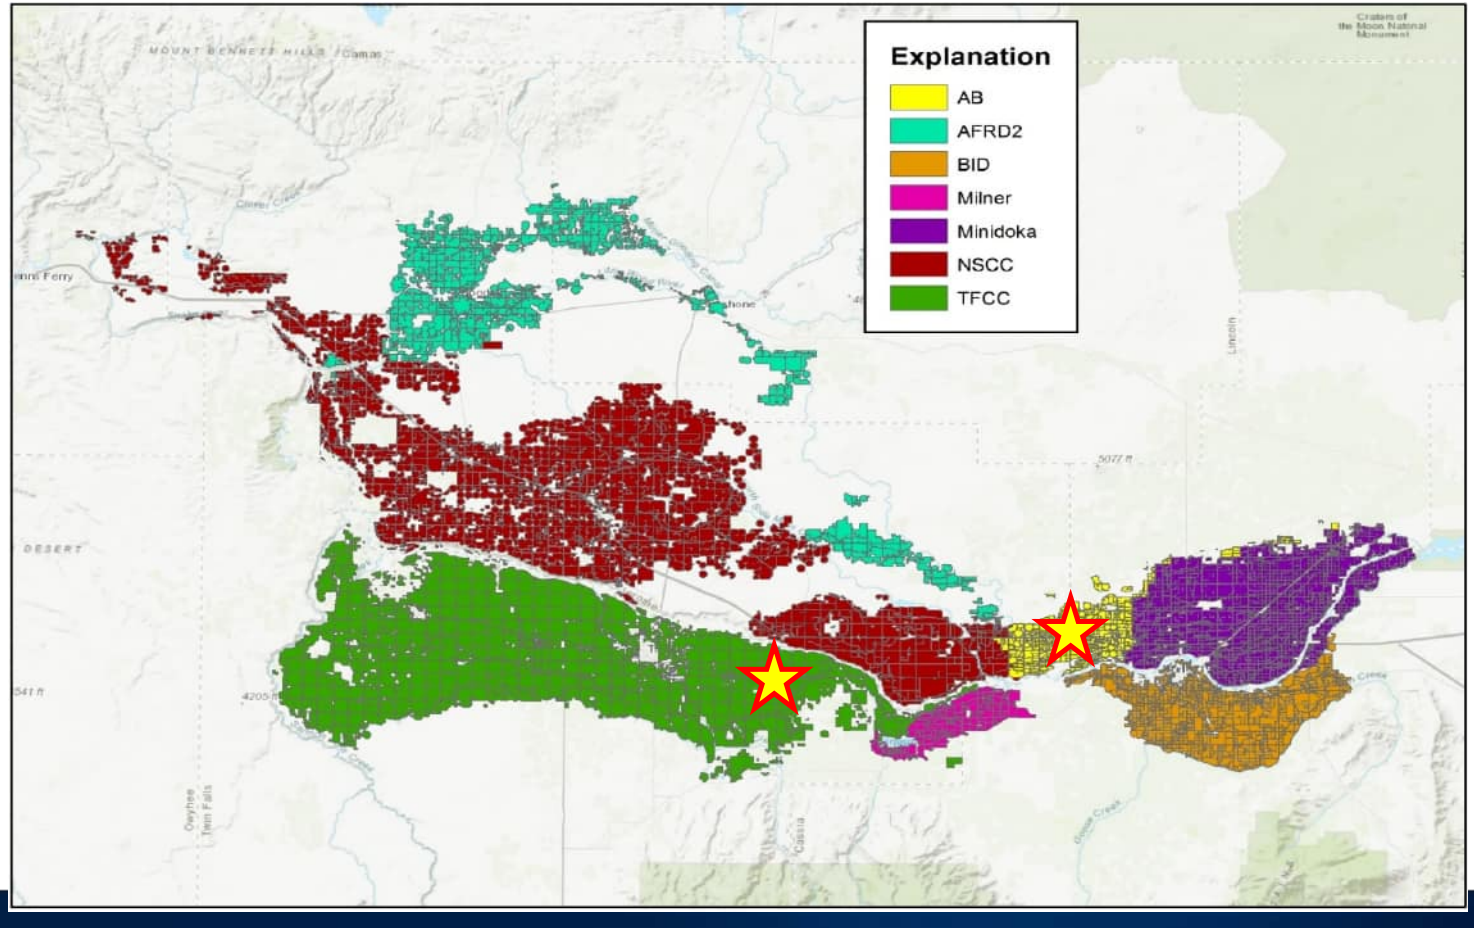
Methodology Reference

- Crop Water Need (CWN) (Page 14 of Methodology)
  - Volume of irrigation water required for crop growth within a SWC entity boundary, such that crop growth is not limited by water availability.
  - CWN_{crop} = (ET_{crop}- Effective Precipitation) * $Acres_{crop}$

- Acres of a Crop (Page 15 of Methodology)
  - The areas for individual crop types will be derived from published crop distributions from the USDA annual crop-specific land cover digital dataset called the Cropland Data Layer (CDL).

Current Method Crop Water Need

$$CWN_{crop} = (ET_{crop} - \text{Effective Precipitation}) * Acres_{crop}$$



- AgriMet ET
- Daily data from Rupert & Twin Falls stations.

- AgriMet Precipitation
- Daily data from Rupert & Twin Falls stations.
- Calculate monthly effective precipitation.

- USDA Crop Data Layer (CDL)
- Remove data speckling and assign the majority crop in each polygon.
- Remove non-irrigated land from CDL using the IDWR Irrigated Lands Dataset.
- Clip CDL to SWC service areas.
- Determine the 3-year average crop mix percentage
- Acres of Each Crop = Crop Mix % * Acres From Methodology

Current Method Crop Water Need

- Significant Shortcomings
  - ET and precipitation from Rupert & Twin Falls stations assumed to represent entire SWC service area.

Current Method Crop Water Need

- Significant Shortcomings - continued
  - CDL is from previous year.
  - Irrigated acres datasets for SWC sometimes represent service areas, not the actual irrigated land.

SWC Member	Created by SWC or IDWR PPU	Date of Shapefile	Shapefile Acres	Methodology Acres
A&B	PPU	2010	21,972	15,924
AFRD2	PPU	2010	69,077	62,361
Burley	SWC	2013	46,035	46,035
Milner	PPU	2010	13,264	13,335
Minidoka	SWC	2022	74,849	75,060
NSCC	PPU	2010	224,463	154,067
TFCC	SWC	2013	194,727*	194,732

* After NRT METRIC processing 179,000 acres.

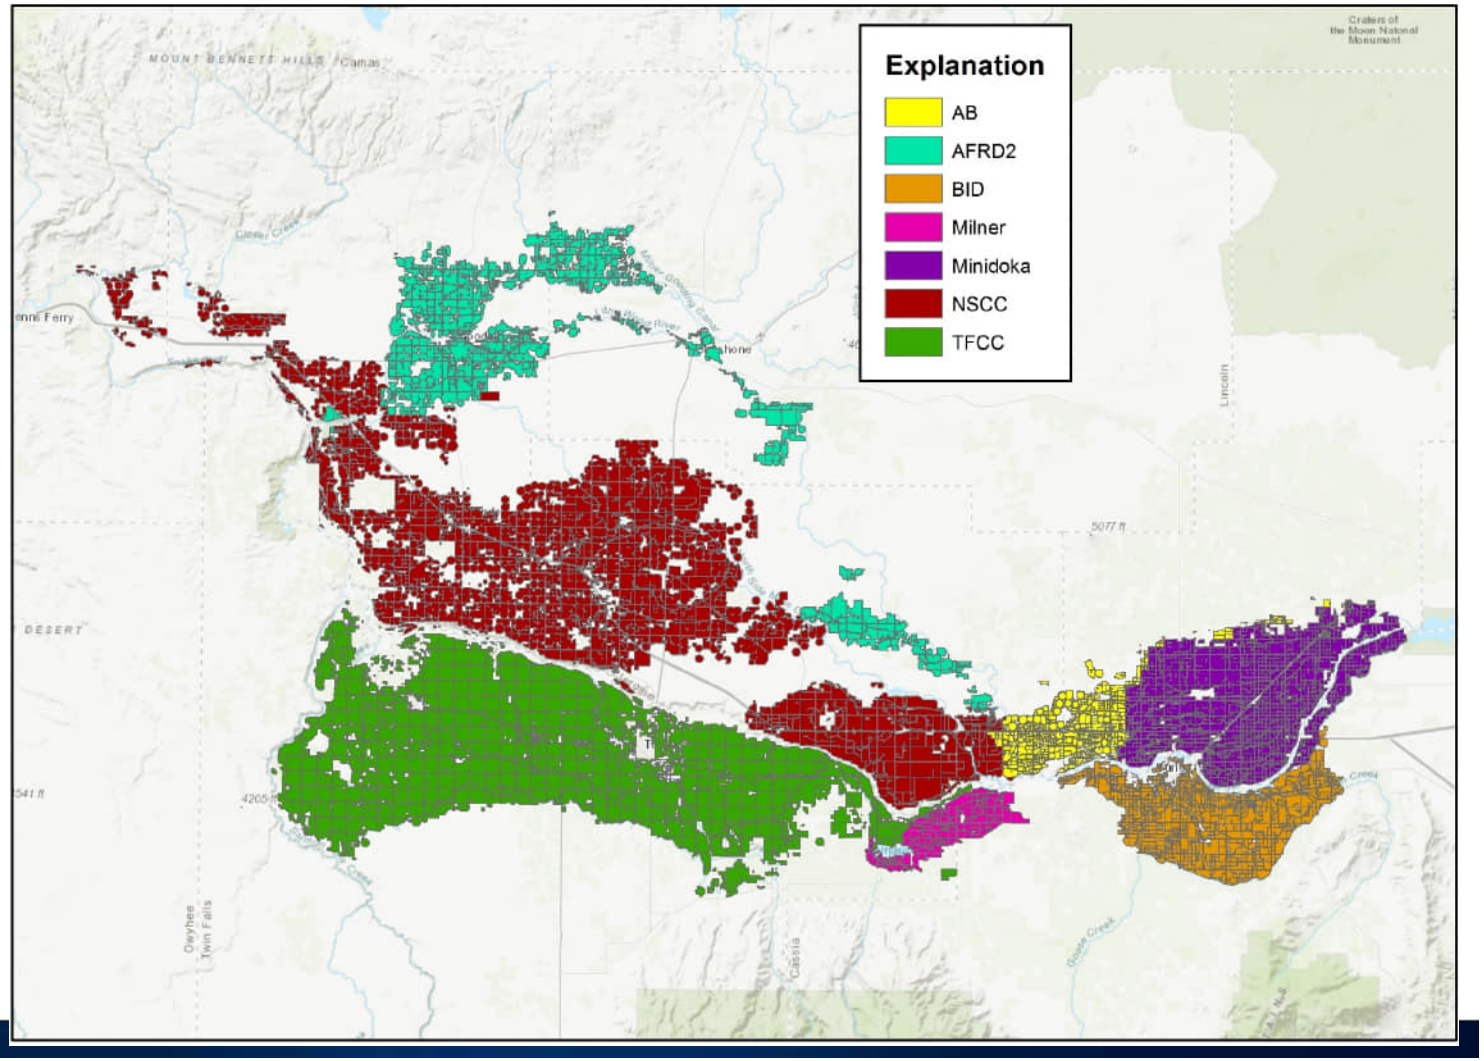
Proposed Method - Near Real Time METRIC

Mapping **E**vapo**T**ranspiration at high **R**esolution and **I**nternalized **C**alibration

- METRIC
  - Developed by Rick Allen et al. in 2007 at the University of Idaho
  - Uses Landsat imagery
  - Utilizes the surface energy balance to calculate ET
  - “Internalized Calibration” ties ET to weather data
  - Calculates ET at a 30-meter scale
- Near Real Time (NRT) METRIC
  - METRIC processed at the end of each month during the irrigation season

Proposed Method NRT METRIC Crop Water Need

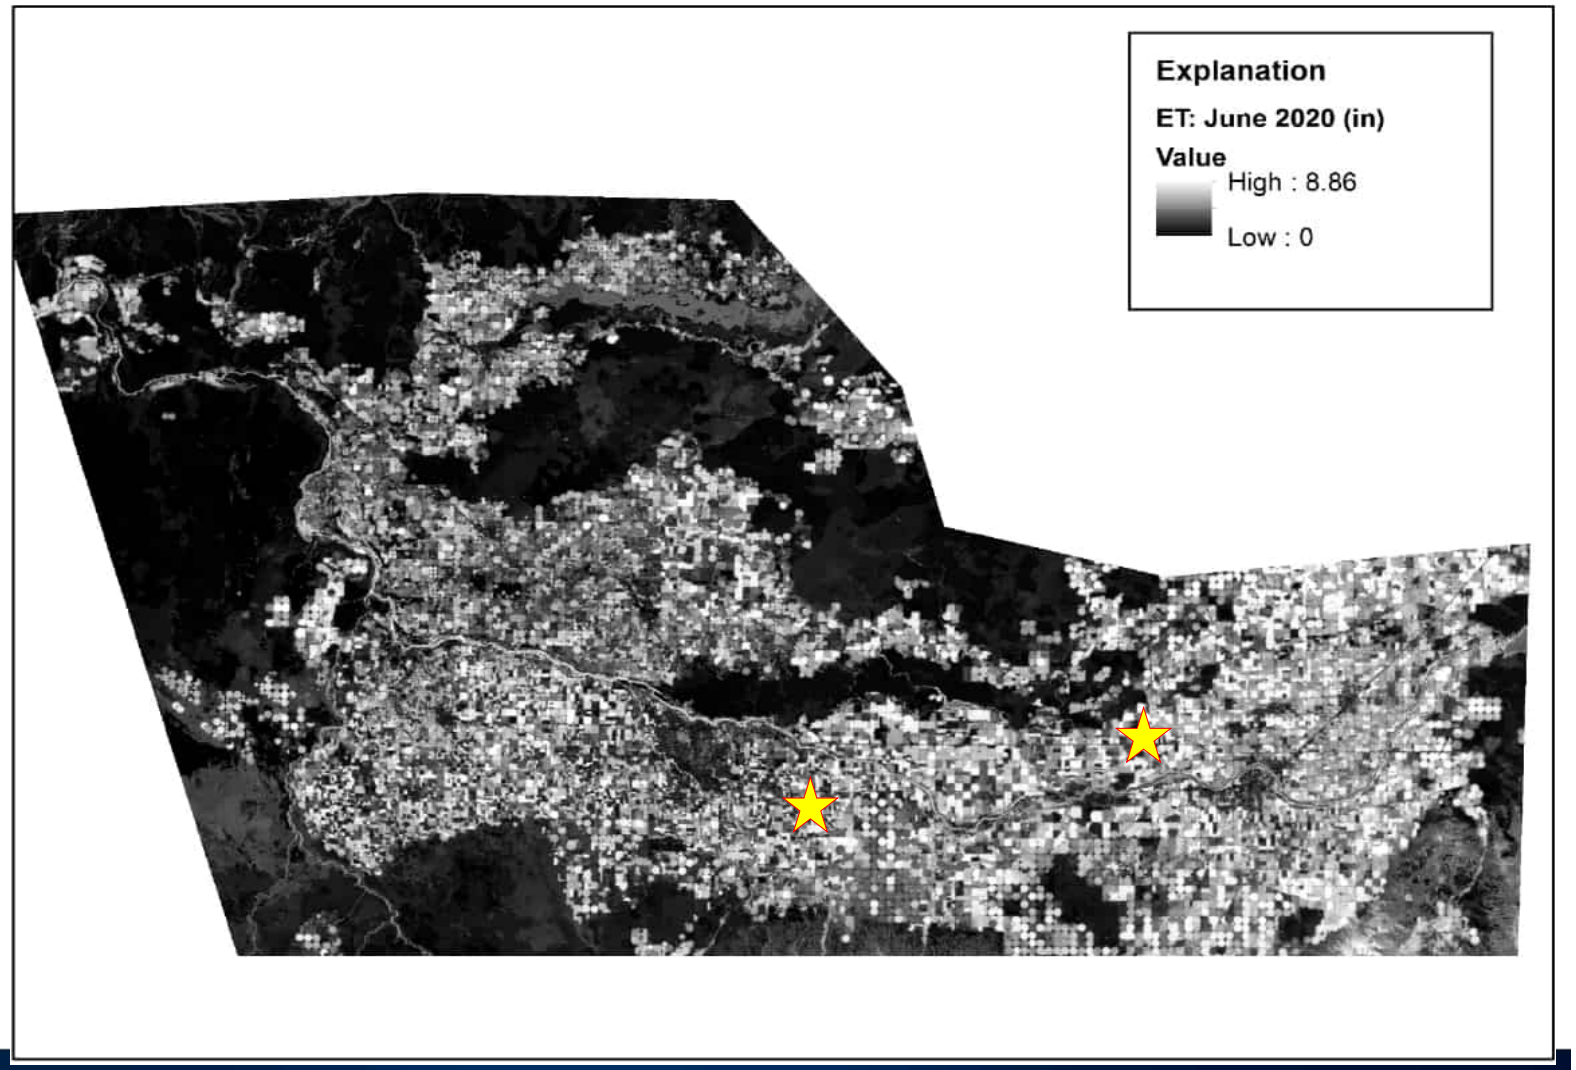
CWN = (ET - Effective Precipitation) * Acres



- NRT METRIC
- Remove non-irrigated land
- Normalize “ET – Effective Precipitation” to AF/Acre for each SWC member

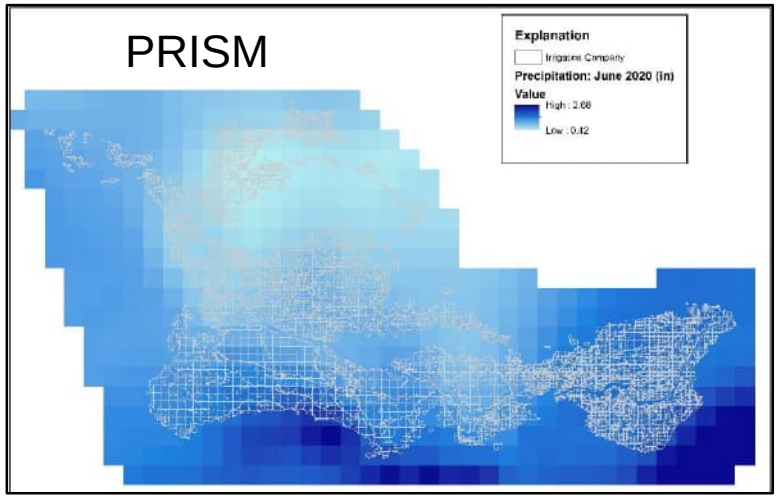
- Irrigated acres from methodology

- Oregon State University Prism Precipitation
- Calculate monthly effective precipitation



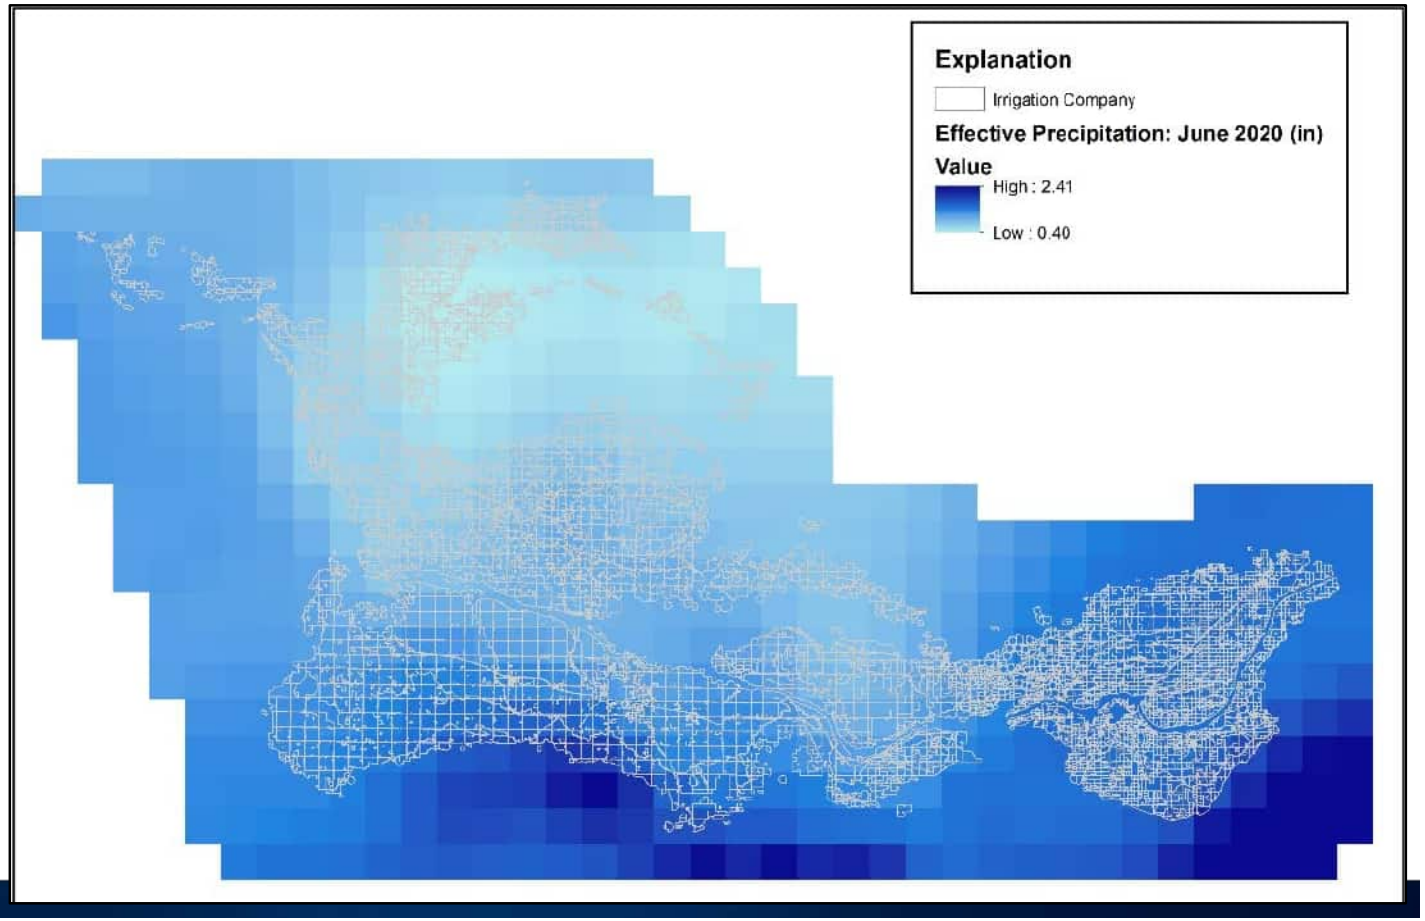
Irrigation Company Service Areas

- Shapefiles are from SWC members and IDWR water right PPU

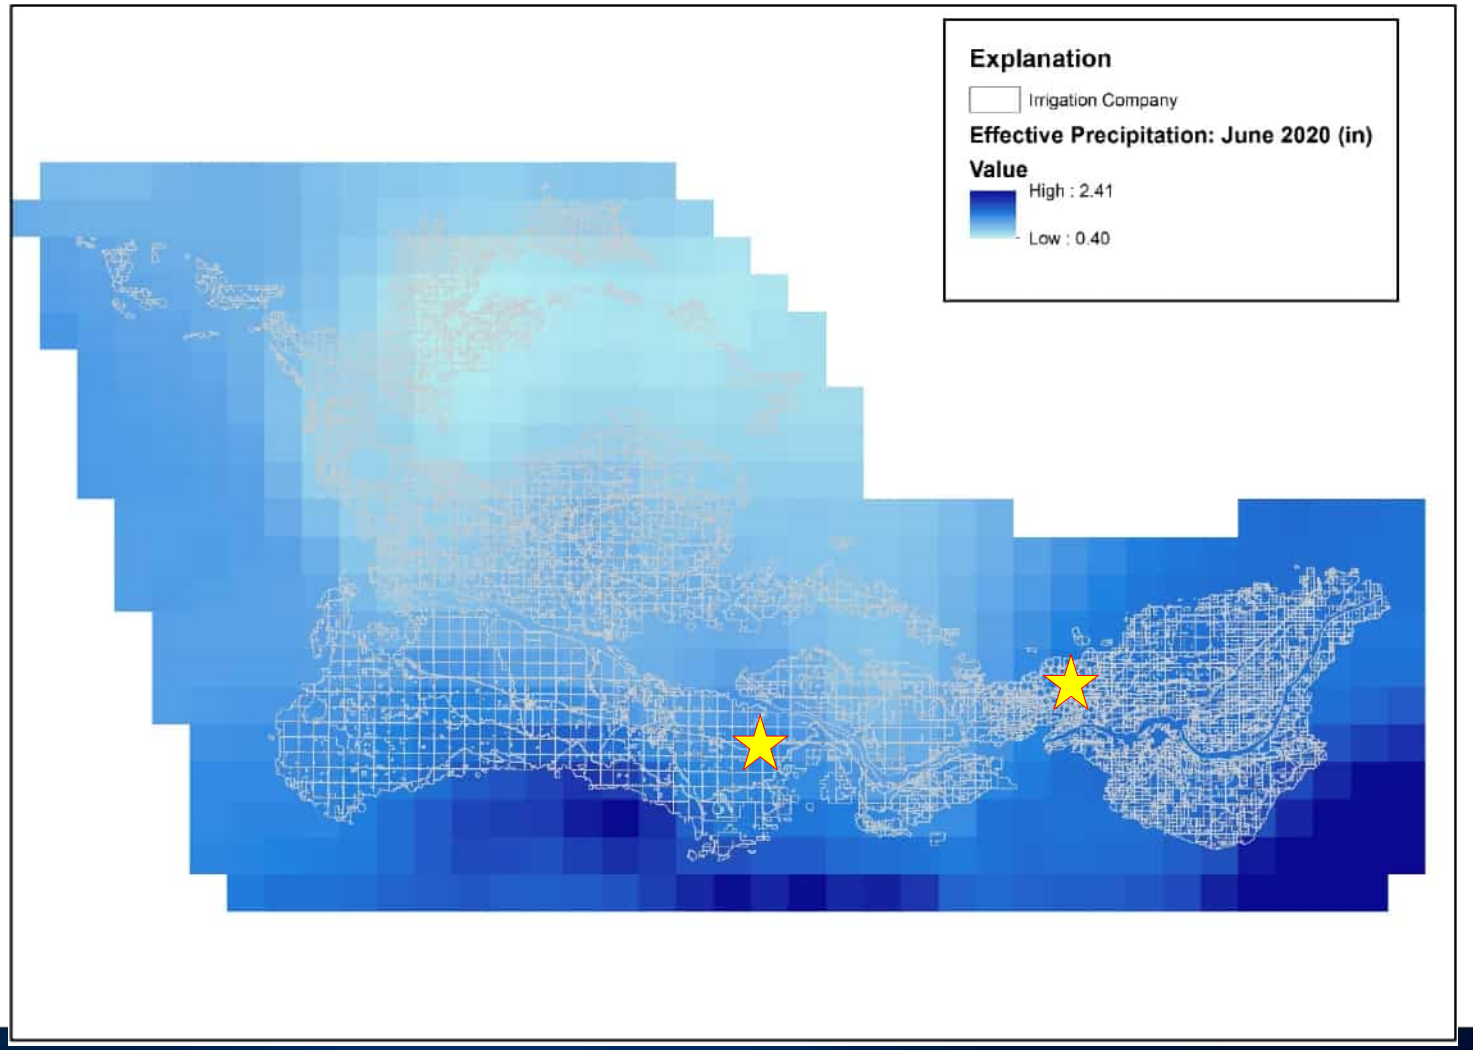


Near Real Time (NRT) METRIC

- Spatial variability is well represented

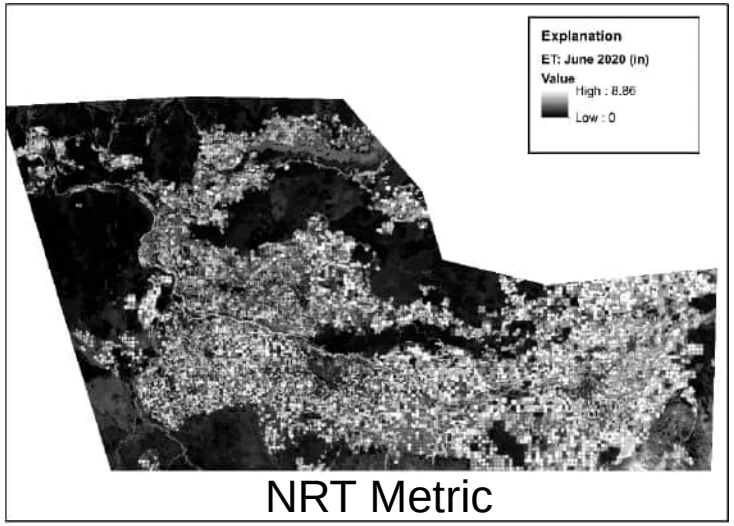


Effective Precipitation: Applied to PRISM

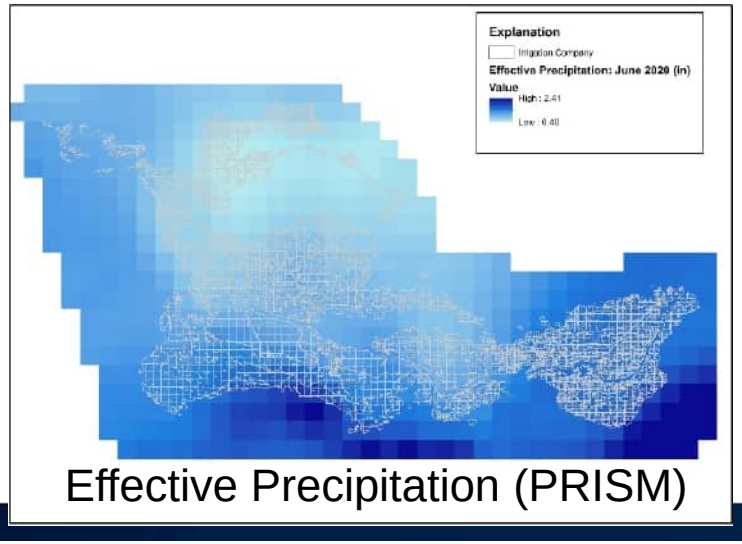


USDA Technical Bulletin 1275		
Total Monthly Precipitation (in)	Percent Effective	Total Monthly Effective Precipitation (in)
1	95%	0.95
2	90%	1.85
3	82%	2.67
4	65%	3.32
5	45%	3.77
6	25%	4.02
>6	5%	

- Similar process used in the CDL method

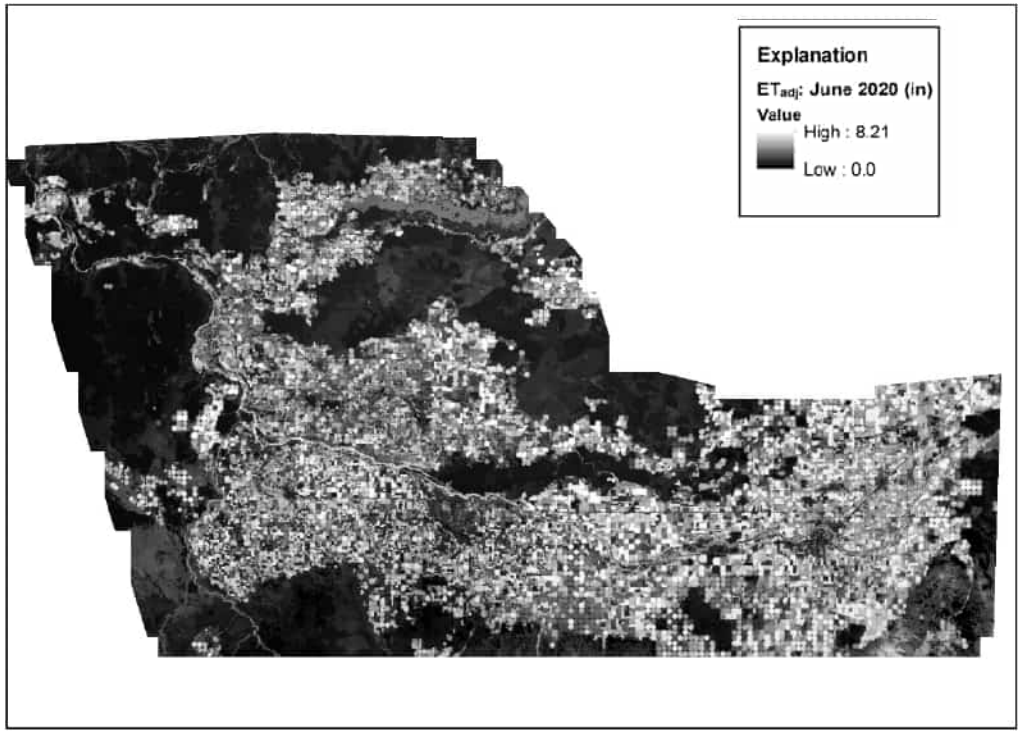


PRISM Effective Precipitation

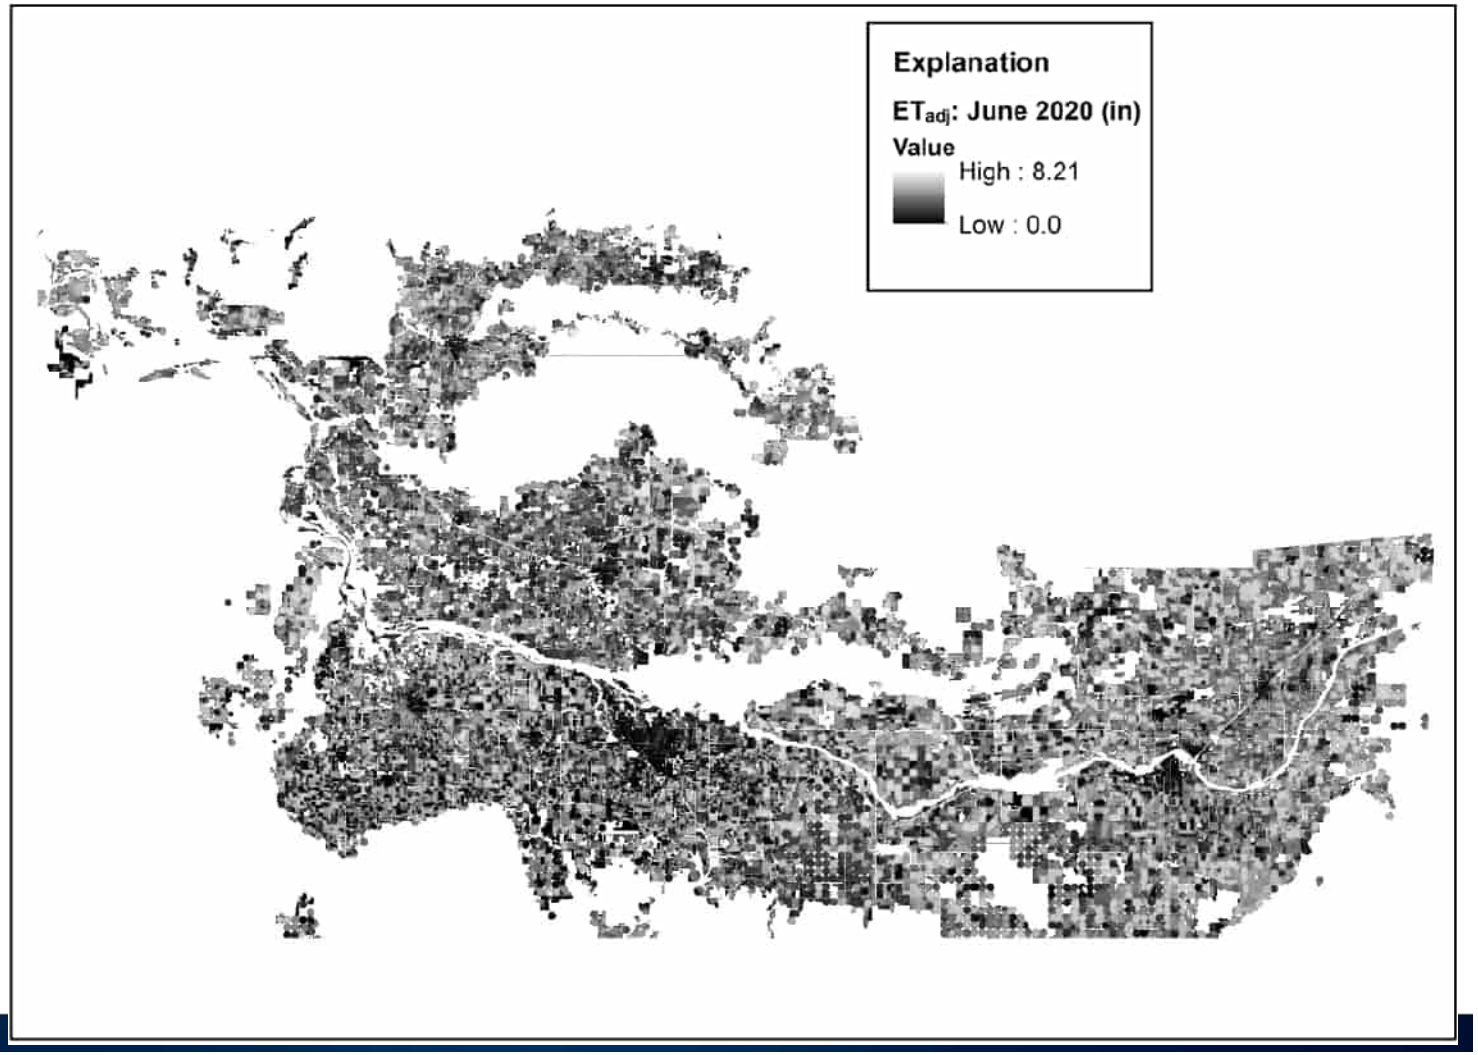


- Spatial coverage is better than the CDL method, which uses two AgriMet Stations (Rupert and Twin Falls)

NRT METRIC – Effective Precipitation (PRISM)

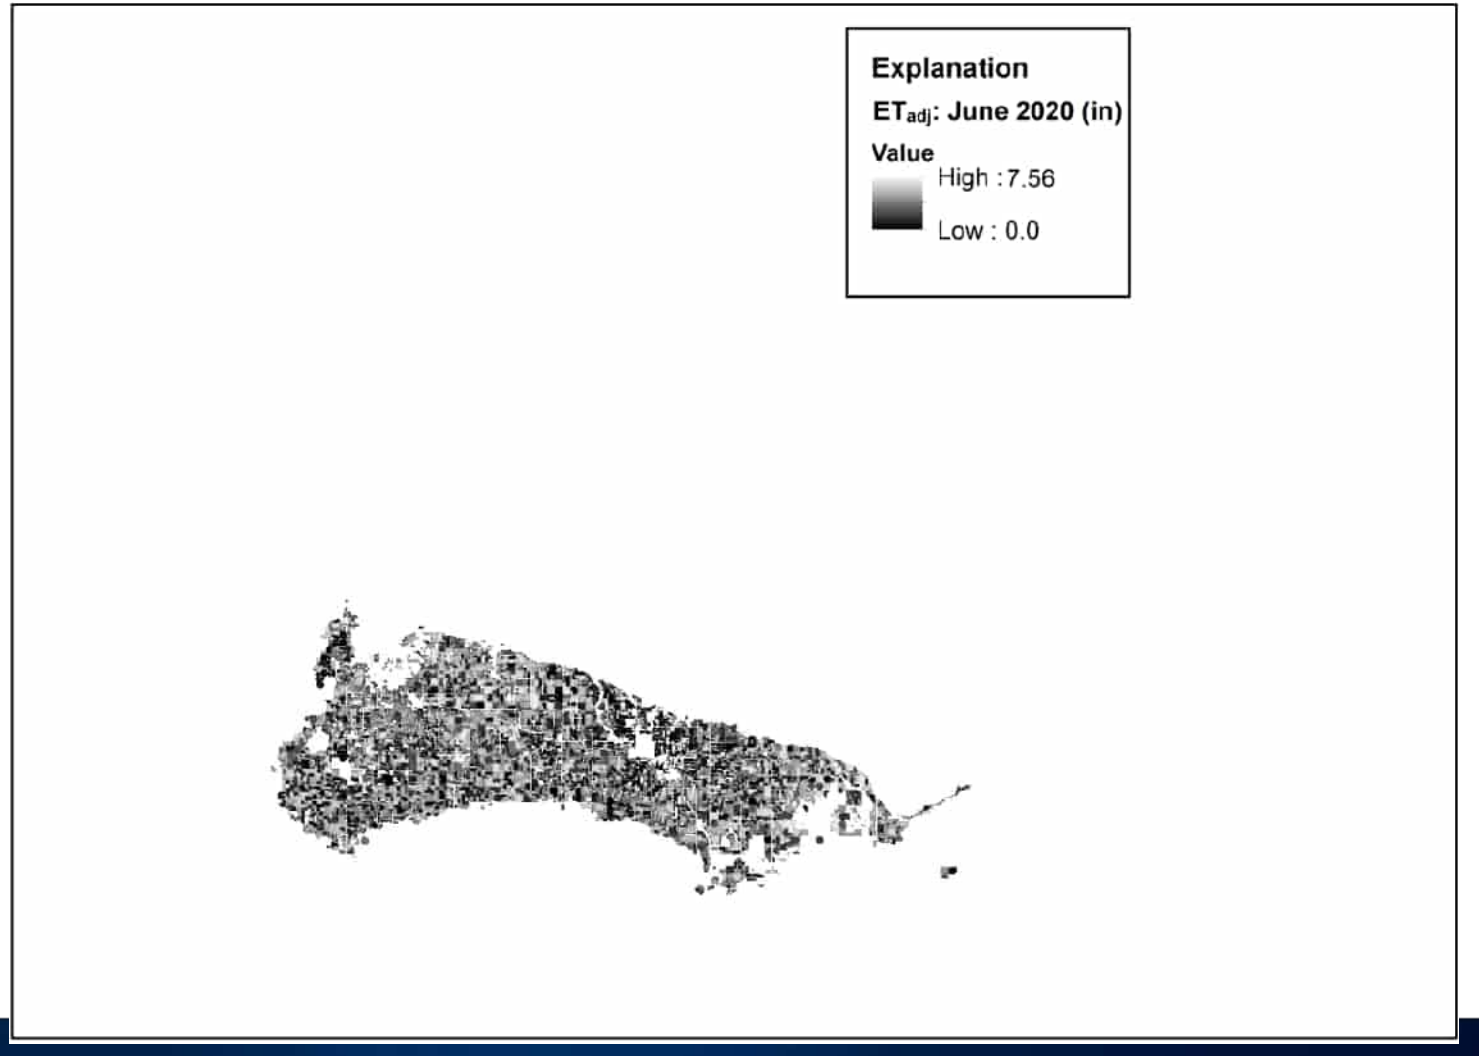


NRT Metric



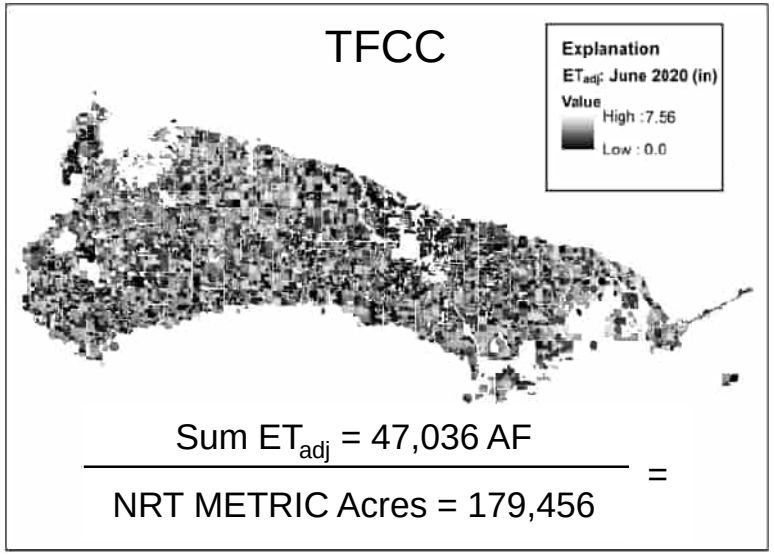
Effective Precipitation (PRISM)

- NRT Metric ET – PRISM Effective Precipitation = ET_{Adj}

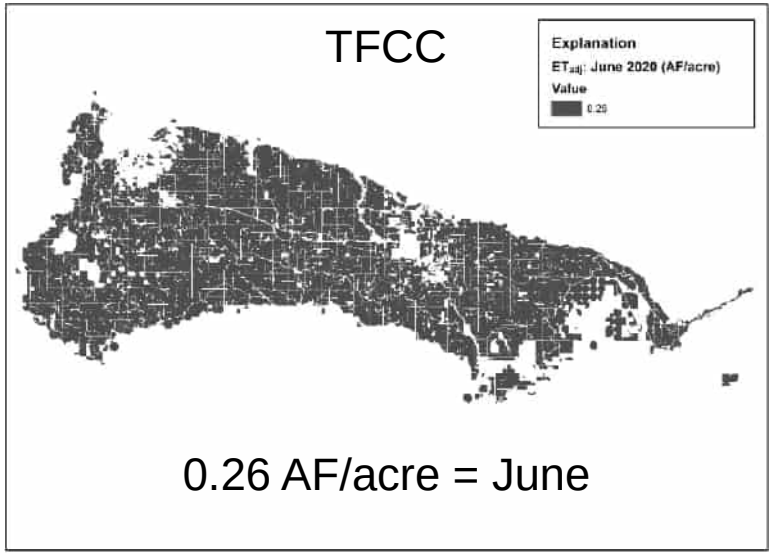


Remove non-irrigated lands

- Remove non-irrigated lands using the IDWR Irrigated Lands dataset



Crop the dataset to each Irrigation Company



- Example: Twin Falls Canal Company

Normalize to AF/acre to apply to Irrigated Acres in the Methodology

$$\frac{\text{Sum } ET_{adj} = 47{,}036 \text{ AF}}{\text{NRT METRIC Acres} = 179{,}456} =$$

0.26 AF/acre = June

- Similar normalization process used in the CDL method
  - Sum ET_{adj} from each Irrigation Company for each month (example: June)
  - Divide the monthly sum by the number of acres in the NRT METRIC dataset
  - Multiply AF/acre value by irrigated acres in the Methodology

Comparison of Results (April-October)

2016 Crop Water Need (AF)

2020	0	0	0	0	0	0
2021	40,491	40,491	162,873	271,198	190,816	457,325

Shortcomings of using NRT METRIC Crop Water Need

- Clouds
  - Extra processing time and possible delays
- Deadlines
  - July 5th
  - August 5th
  - August 20th (Time of Need)
  - Nov 15th
- Data can change in subsequent months in NRT METRIC
  - All SWC Irrigation Companies
    - June: +1.02% to -2.30%
  - TFCC
    - June: -0.21% to -2.12%
- Normalized to AF/acre
  - This process is also performed in the current CDL Method
- By calculating Actual ET with NRT METRIC is the calculation failing to capture a portion of the shortfall in dry years?

Conclusion

- Switching to NRT METRIC is an upgrade.

CDL	NRT METRIC
Average crop mix from the previous 3 years	Eliminates the crop mix variable and uses data from the current year.
Calculates the potential ET assuming the crops are getting a full water supply.	Calculates actual ET of the crops as they are maturing.
Applies ET and precipitation data collected at the Twin Falls and Rupert AgriMet Stations to SWC service areas.	ET and precipitation are spatial datasets that represent conditions throughout the SWC service areas.

CDL vs. NRT METRIC Summary

CDL	NRT METRIC
Download CDL dataset from previous year	---
Process the CDL to remove speckling	---
Remove non-irrigated land from the CDL using the IDWR Irrigated Lands dataset	---
Determine the crop mix for each SWC Member	---
Determine the “3-Year average crop mix” for each SWC Member	---
Download AgriMet Precipitation data	Download Prism Precipitation data
Calculate monthly Effective Precipitation	Calculate monthly Effective Precipitation
Download AgriMet ET data	Obtain NRT METRIC ET data
Subtract monthly Effective Precipitation from ET	Subtract monthly Effective Precipitation from ET
---	Remove non-irrigated land from the “ET – Effective Precipitation” dataset using the IDWR Irrigated Lands dataset
---	Calculate “ET – Effective Precipitation” in Acre-Feet for each SWC Member
Determine the number of acres of each crop grown by each SWC member by multiplying the “3-Year average crop mix” for each SWC Member by the number of acres used for the Methodology	Normalize the “ET – Effective Precipitation” for each SWC member to the number of acres used for the Methodology
Calculate “ET – Effective Precipitation” in Acre-Feet for each SWC Member	---

IDAHO Department of Water Resources

IDAHO DEPARTMENT OF WATER RESOURCES

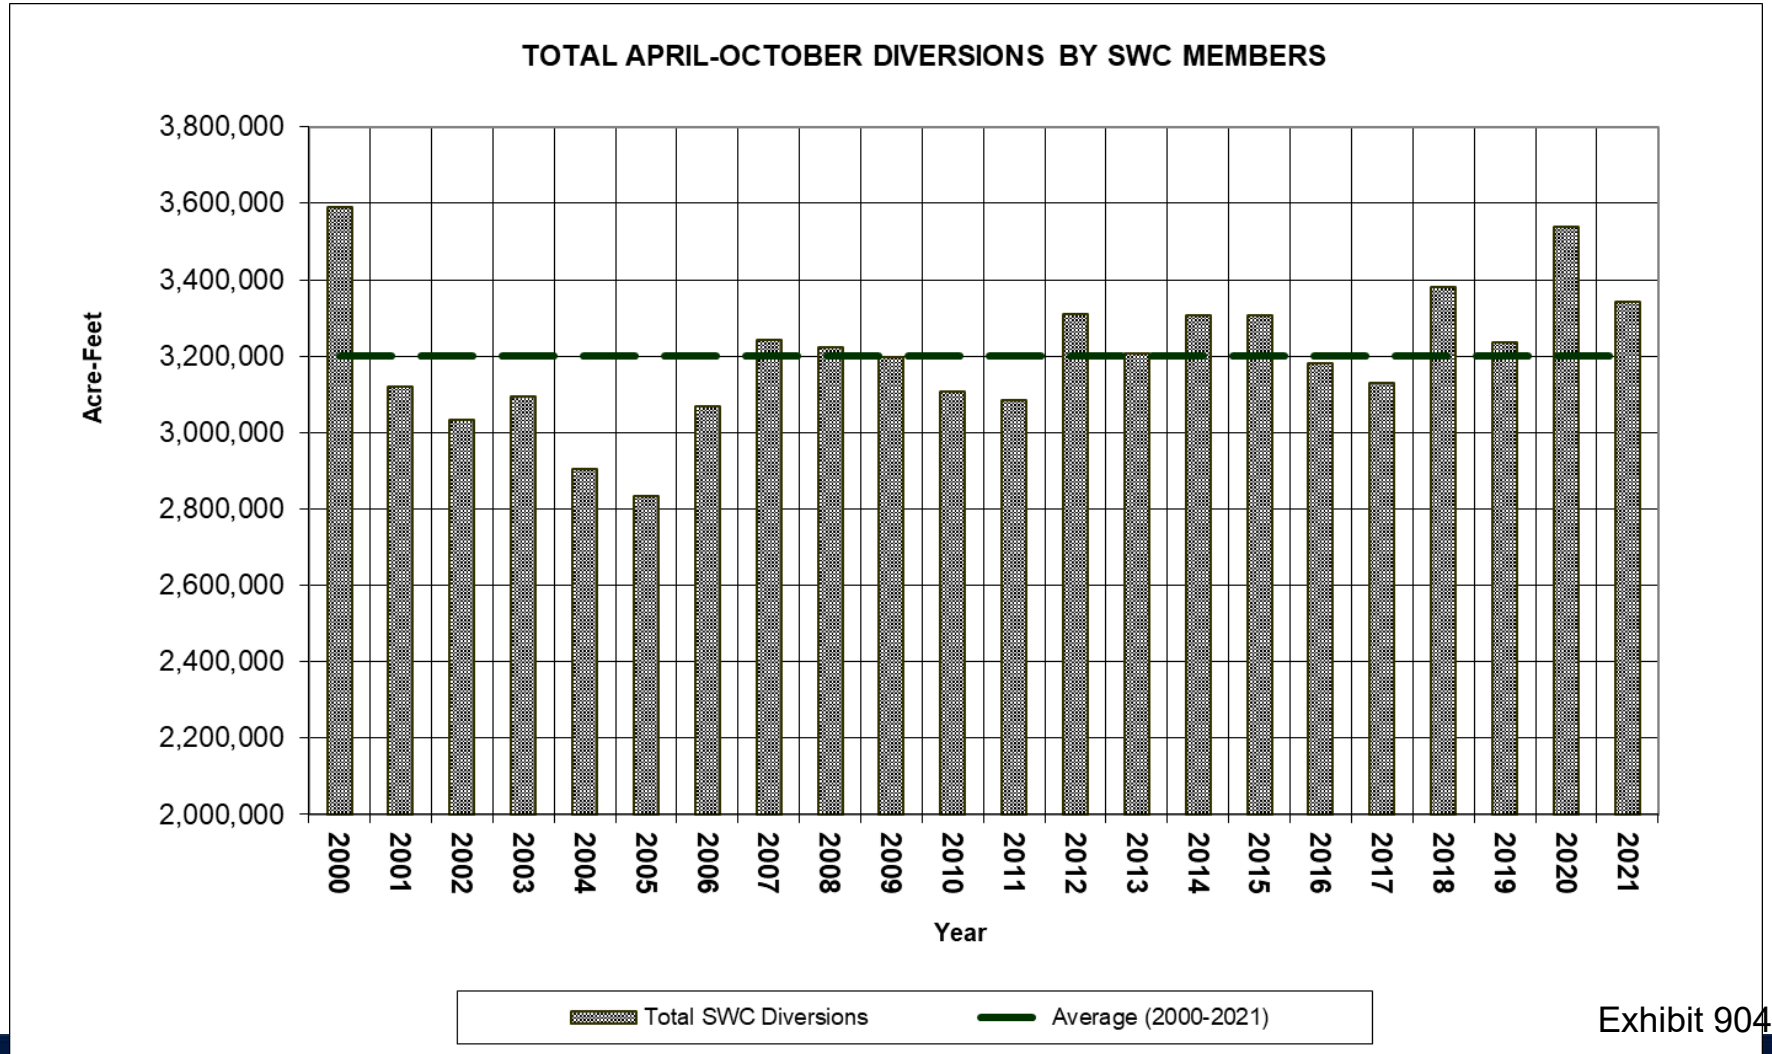
Proposed Modification of the Methodology For Determining Material Injury To Reasonable In-Season Demand and Reasonable Carryover: Baseline Year

Presented by: Matt Anders

Date: 11/16/2022

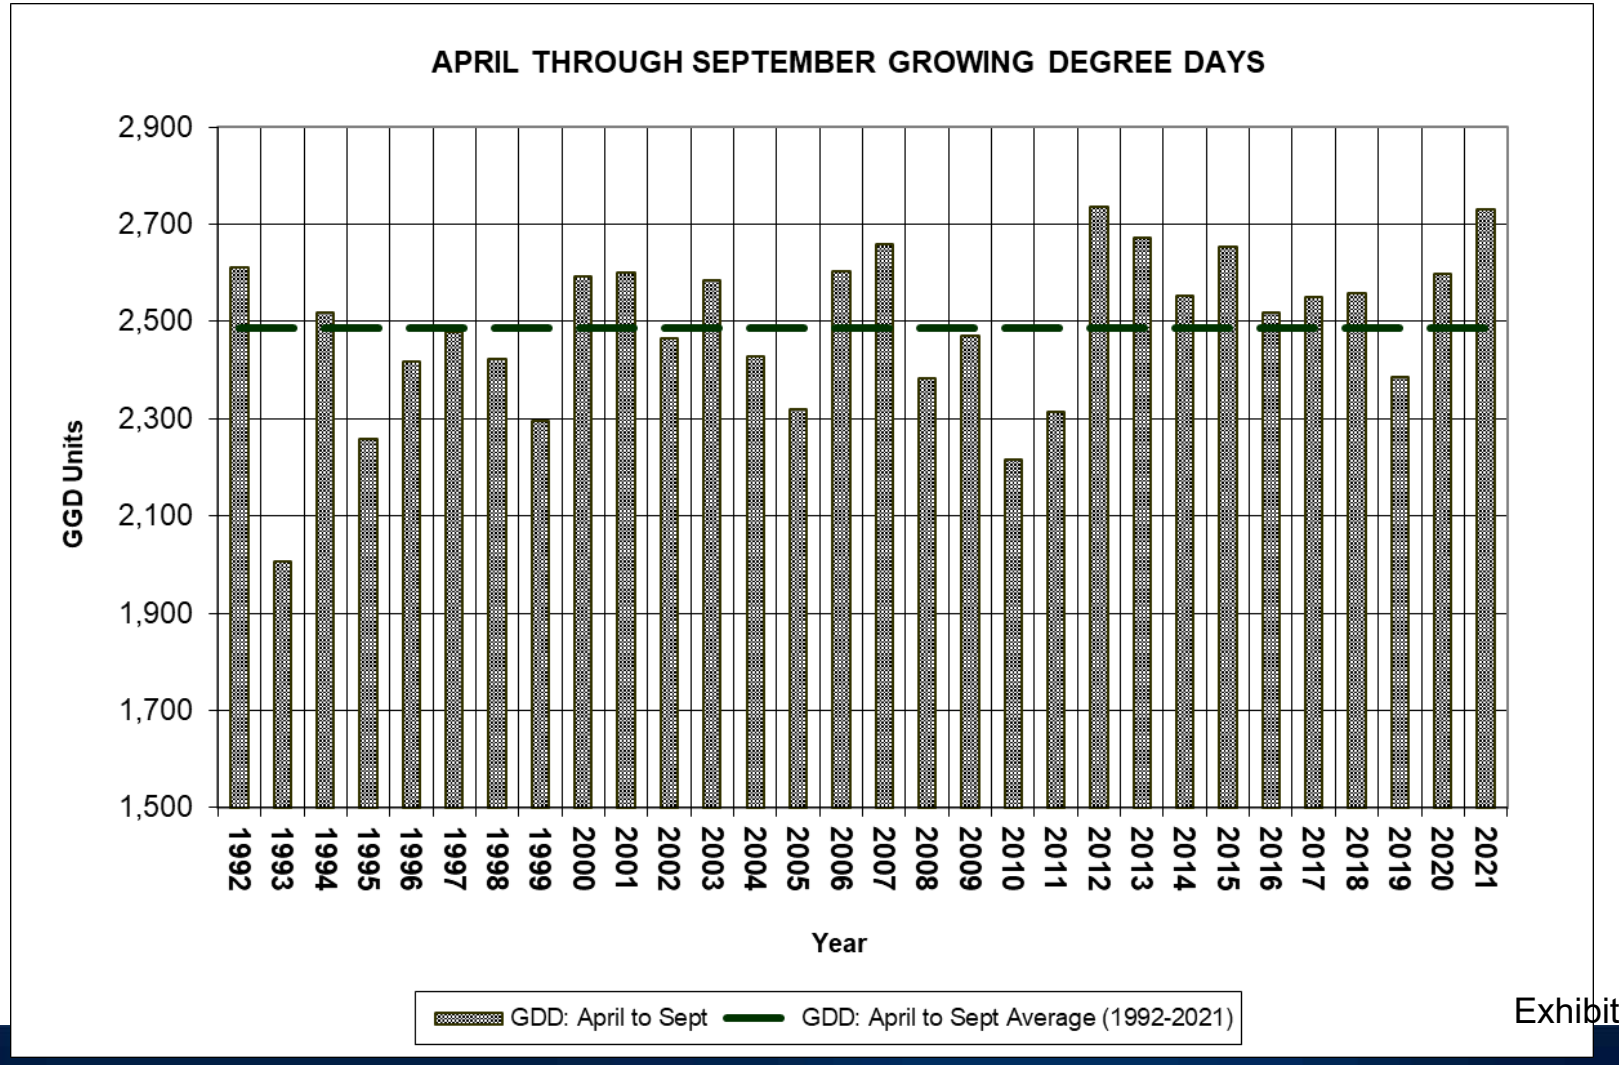
Elements of Shortfall Calculation – Baseline Year (BLY)

Milestone	Supply	Reasonable In-Season Demand (RISD)
April	Forecast Natural Flow (Apr-Oct) • Regression Equations Predicted Storage Allocation • Analogous Year or Years	Predicted Demand (Apr-Oct) • Historical Demand from Baseline Year (BLY)
July	Actual Diverted Natural Flow (Apr-June) Forecast Natural Flow (July-Oct) • Regression Equations Storage Allocation • Storage Report or Analogous Year	Crop Water Need (Apr-June) • ET • Precipitation • Project Efficiency Predicted Demand (July-Oct) • Historical Demand from Baseline Year (BLY)



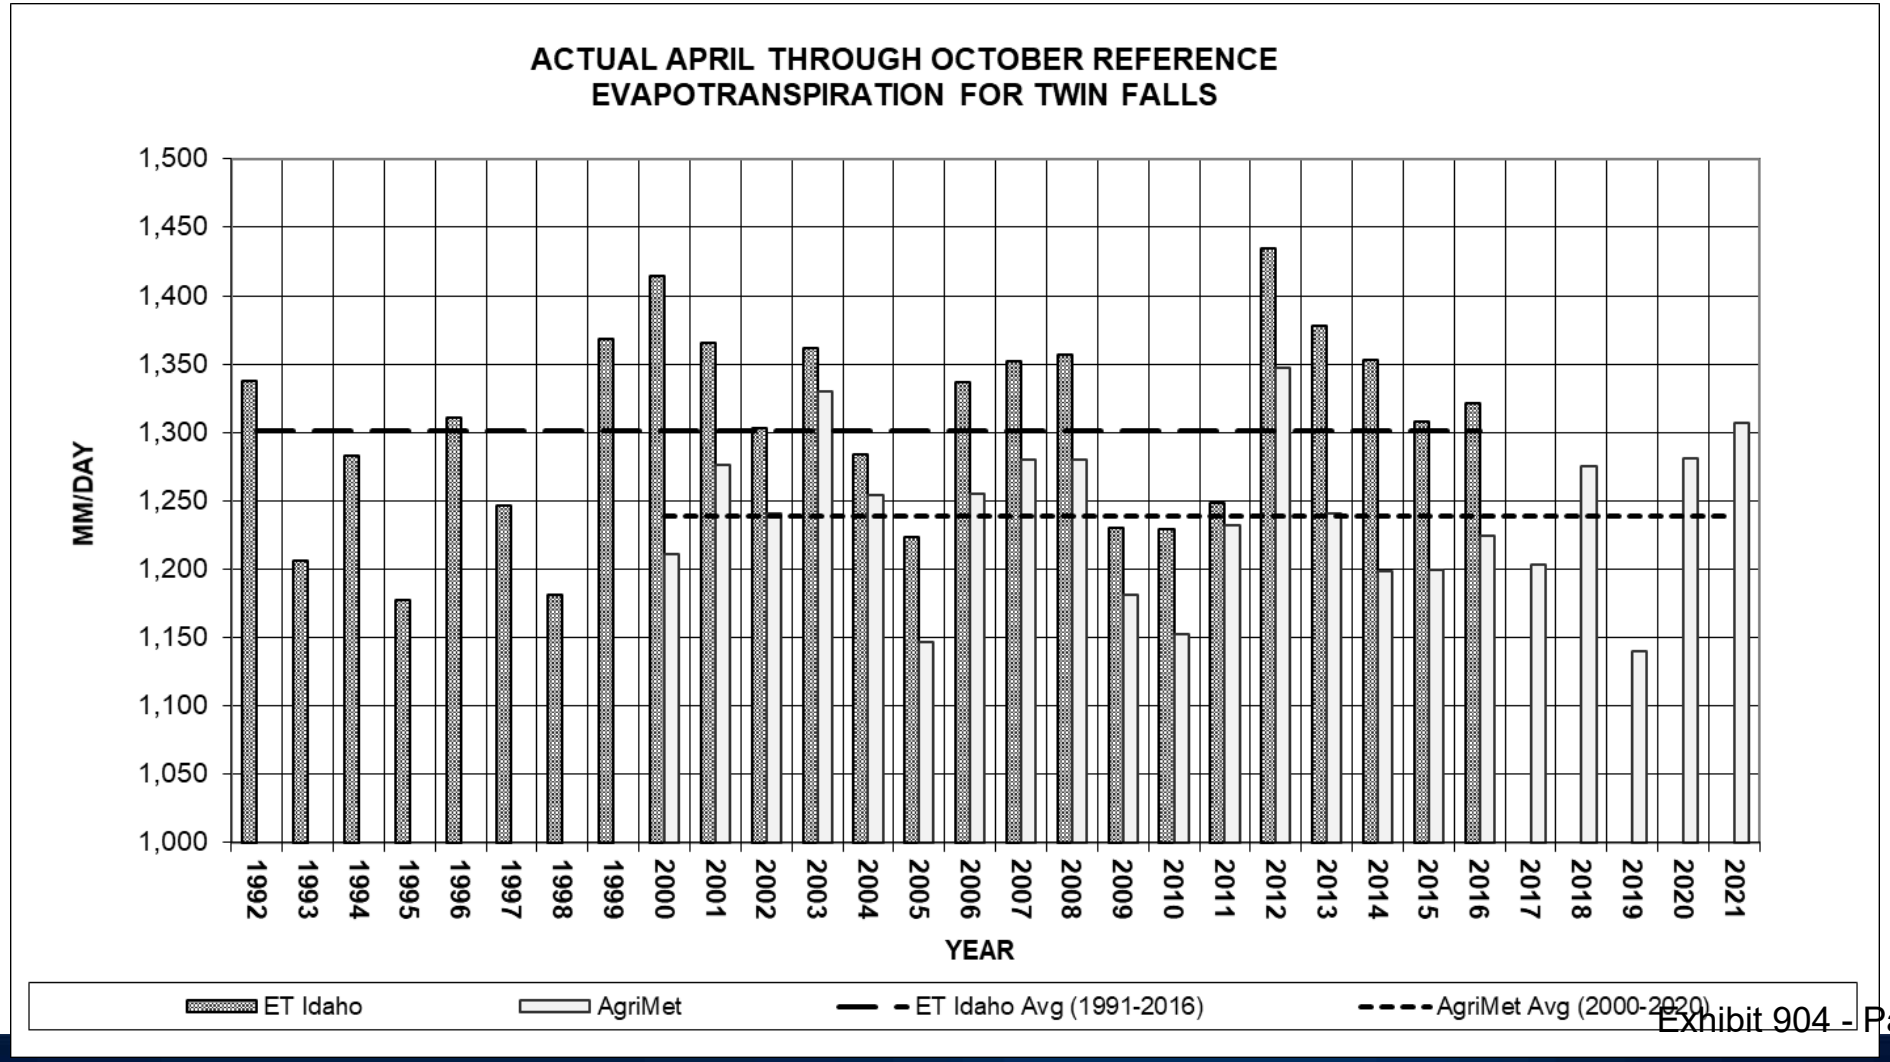
Elements of Shortfall Calculation – Baseline Year (BLY)

Milestone	Supply	Reasonable In-Season Demand (RISD)
Time of Need	Actual Diverted Natural Flow (Apr-Time of Need) Forecast Natural Flow (Time of Need-Oct) • Natural Flow from Comparable Year Storage Allocation • Storage Report	Crop Water Need (Apr-Time of Need) • ET • Precipitation • Project Efficiency Predicted Demand (Time of Need-Oct) • Historical Demand from Baseline Year (BLY)
November	Actual Diverted Natural Flow (Apr-Oct) Storage Allocation • Storage Report	Crop Water Need (Apr-Oct) • ET • Precipitation • Project Efficiency

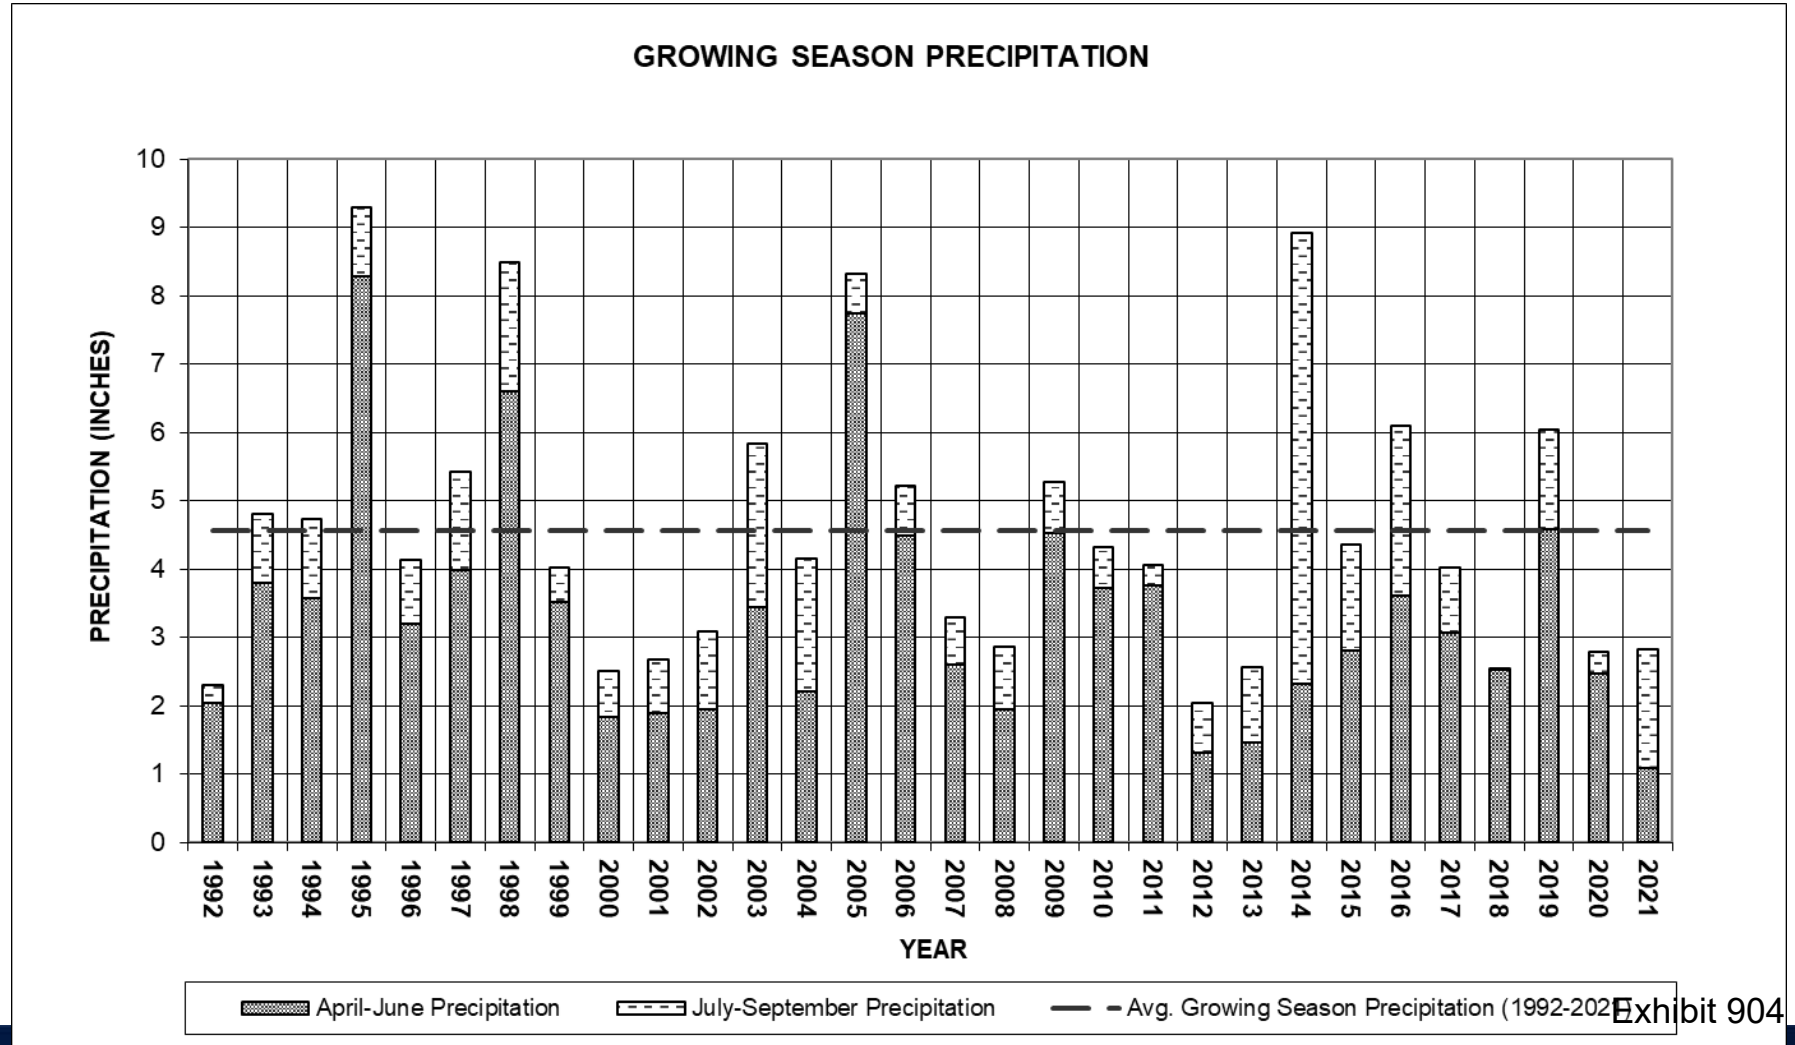


Methodology Reference

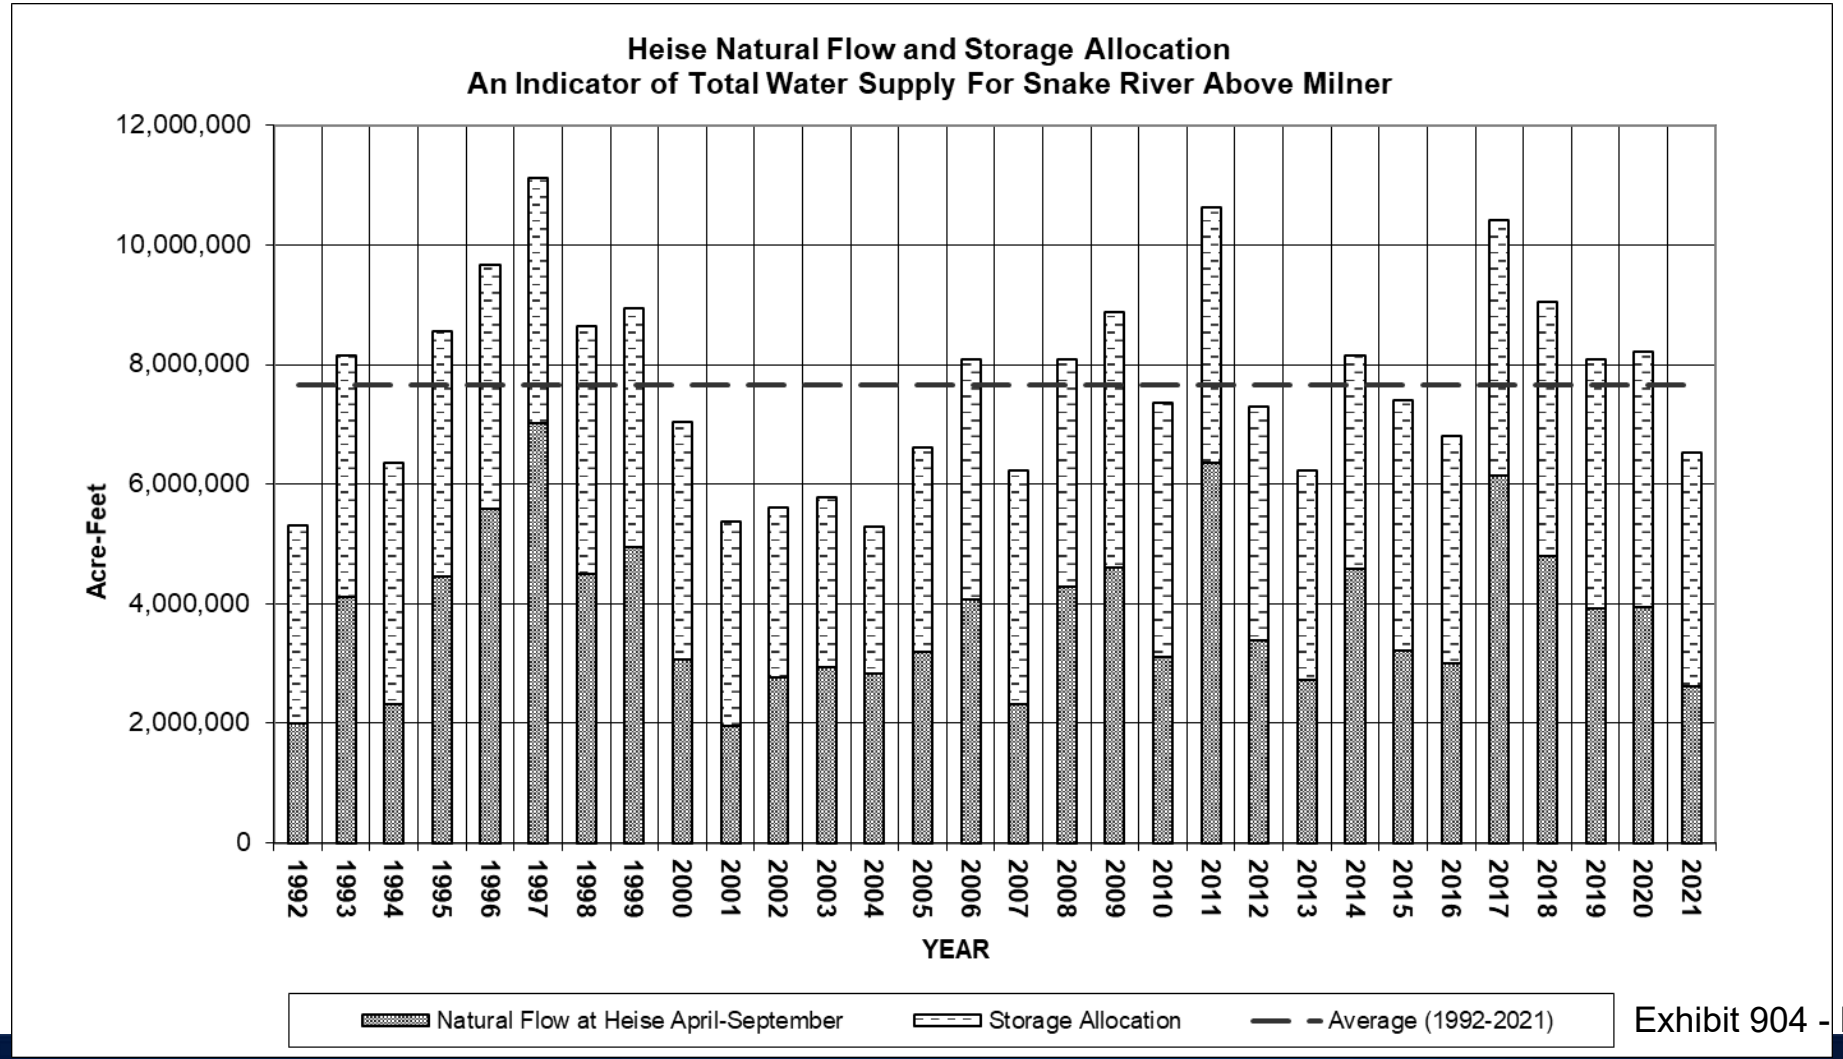
- Baseline Year (BLY) (Page 5 of Methodology)
  - Finding of Fact 7: A BLY is a year or average of years when irrigation demand represents conditions that can be used to predict need in the current year of irrigation at the start of the irrigation season.
  - Finding of Fact 9: Intended to shift risk to junior water right holders.
- Used in methodology calculation to predict irrigation demand
  - April
  - July
  - Time of Need
- BLY Criteria
  - Above average
    - Diversions
    - Temperatures (Growing Degree Days)
    - ET
  - Below average precipitation
  - Not a year of limited supply



Diversions (Above Average)



Growing Degree Days (Above Average)



Reference ET (Above Average)

Precipitation (Below Average)

Supply Not Limited (Above Average)

BLY Criteria Data Ranges

- BLY Criteria
  - Above average
    - Diversions — 2000-2021
      - Finding of Fact 8 (page 5) & Finding of Fact 20 (page 10):
        To capture current irrigation practices…selection of a BLY should be limited to years subsequent to 1999.
    - Temperatures (Growing Degree Days) — 1992-2021
    - ET — 1992-2021
  - Below average precipitation — 1992-2021
  - Not a year of limited supply — 1992-2021

Diversions

	A&B (AF)	AFRD2 (AF)	BID (AF)	Milner (AF)	Minidoka (AF)	NSCC (AF)	TFCC (AF)	Total (AF)

BLY % of Average 2000-2021	100.9%	100.0%	101.8%	87.6%	104.2%	98.2%	99.8%	99.8%

- Finding of Fact 25 (page 11): When compared to the average diversion from 2000-2014, the 06/08 diversions are no longer above average.
- 06/08/12 can no longer be the BLY because diversions are no longer above average.

BLY Selection Criteria

Year	Above Average ∑SWC Diversions (2000-2021)	Above Average GDD (1992-2021)	Above Average ET (1991-2021)	Below Average Precipitation (1992-2021)	Above Average Heise Runoff (1992-2021)	Supply Not Limited (Above Average) (1992-2021)	Notes
2000	x	x		x			
2001		x	x	x			
2002			x	x			
2003		x	x				
2004				x			
2005							
2006		x	x		x	x	Below average diversions
2007	x	x	x	x			Hot dry Spring, low carryover TFCC
2008	x		x	x	x	x	Below average GGD
2009	x				x	x	
2010				x			
2011				x	x	x	Very Wet
2012	x	x	x	x			Hot dry spring, lowest precipitation, highest ET, most GGD
2013	x	x	x	x			Wet Fall, AFRD2 and TFCC reduced deliveries in-season.
2014	x	x			x	x	Record August Rains
2015	x	x		x			
2016		x					
2017		x		x	x	x	
2018	x	x	x	x	x	x	
2019	x				x	x	
2020	x	x	x	x	x	x	Abnormally high diversions?
2021	x	x	x	x			

* To capture current irrigation practices, identification of a BLY is limited to years subsequent to 1999 (Page 5).

SWC methodology – calculation of priority dates for curtailment of junior groundwater users

Presented to the SWC Methodology Technical Working Group

Jennifer Sukow, P.E., P.G.

November 28, 2022

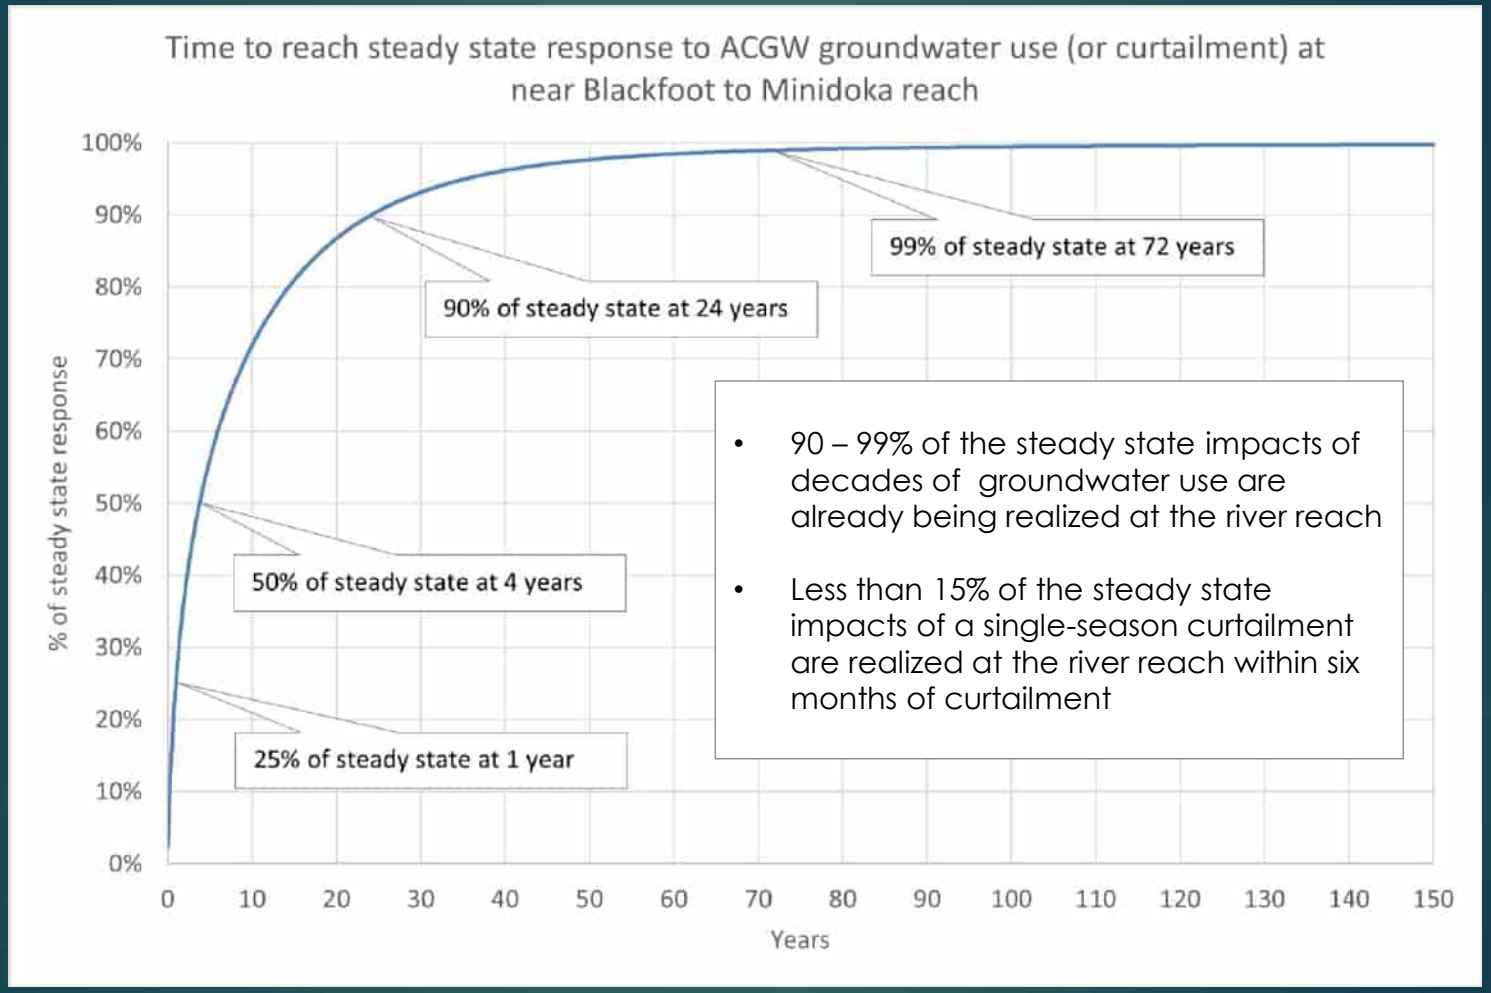
Methodology reference

- Curtailment date calculation (Step 2) (Page 36 of Methodology)
  - The ESPA Model will be run to determine the curtailment date which will produce a volume of water equal to the DS in the near Blackfoot to Minidoka reach. The model simulation will be run at steady state within the area of common ground water supply as described by CM Rule 50.01.
- Curtailment date calculation (Step 6) (Page 38 of Methodology)
  - Upon a determination of an additional mitigation obligation, junior ground water users will be required to establish, to the satisfaction of the Director, their ability to secure a volume of storage water pursuant to an approved mitigation plan or to conduct other approved mitigation activities that will deliver the additional mitigation obligation water to the injured members of the SWC at the Time of Need. If junior ground water users fail or refuse to submit this information within fourteen (14) days from issuance of a Step 6 order, the Director will issue an order curtailing junior ground water users.[13] The ESPA Model will be run to determine the priority date to produce the necessary additional mitigation obligation volume within the area of common ground water supply, as described by CM Rule 50.01.

Methodology reference

- Curtailment for carryover shortfall (Step 9) (Page 39 of Methodology)
  - Fourteen (14) days following the issuance by the Department of reasonable carryover shortfall obligations, junior ground water users will be required to establish, to the satisfaction of the Director, their ability to supply a volume of storage water or to conduct other approved mitigation activities that will provide water to the injured members of the SWC equal to the reasonable carryover shortfall for all injured members of the SWC. If junior ground water users cannot provide this information, the Director will issue an order curtailing junior ground water rights.

Presentation outline

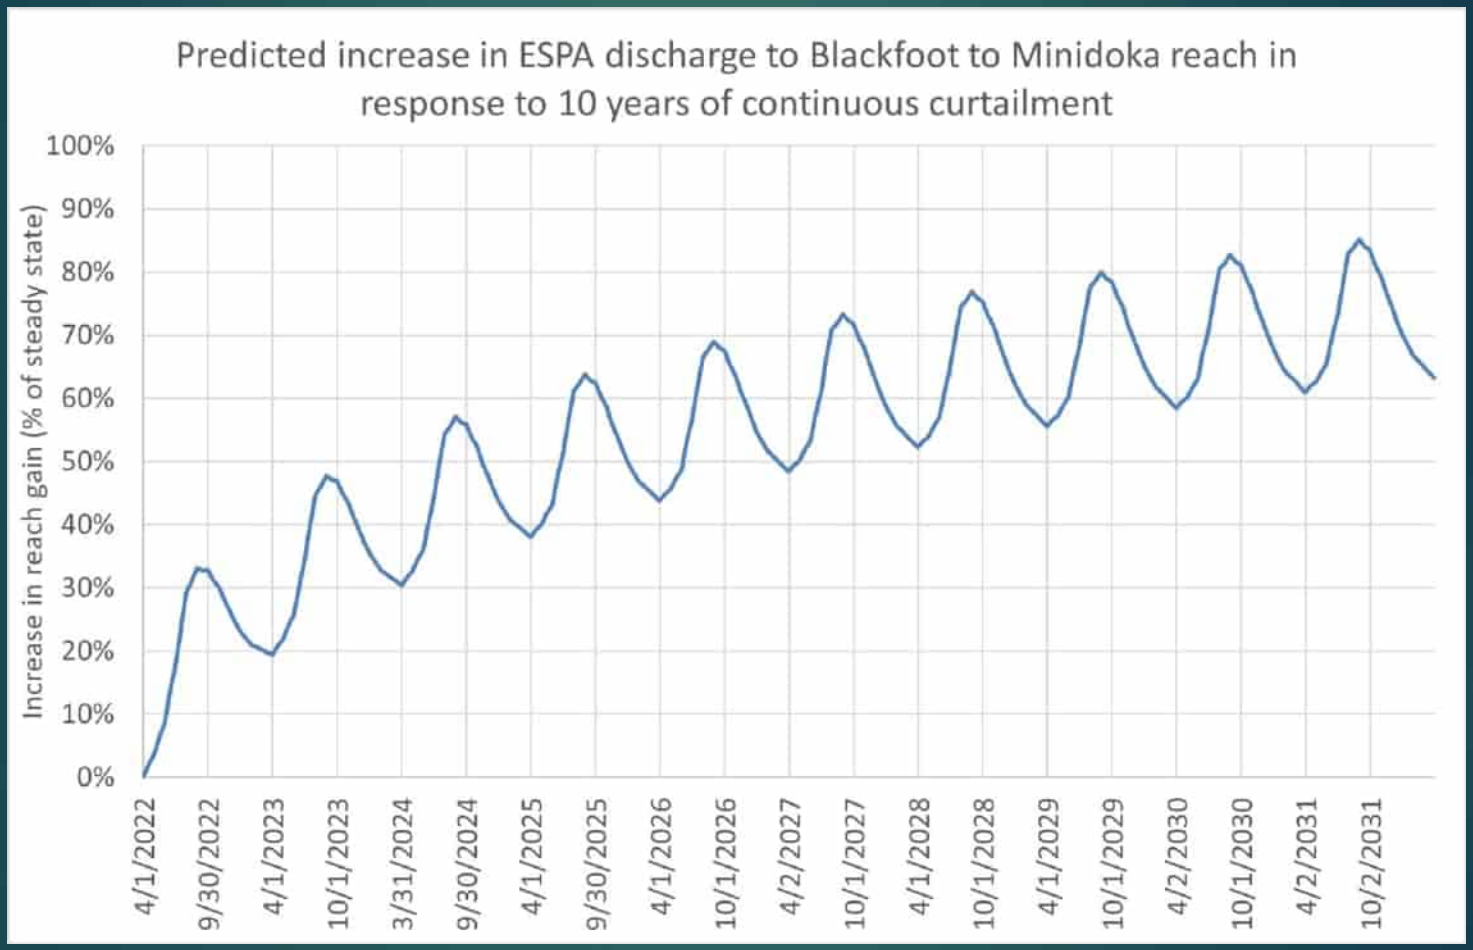


- Steady state vs. transient model simulations
- Transient model results for curtailment priority dates in 2022 orders
- Examples of transient model simulations for calculation of curtailment priority dates
  - Assumptions for transient model simulations
  - Comparison of priority dates and acres curtailed for various shortfall volumes
  - Transient analyses for water years 2021-2022

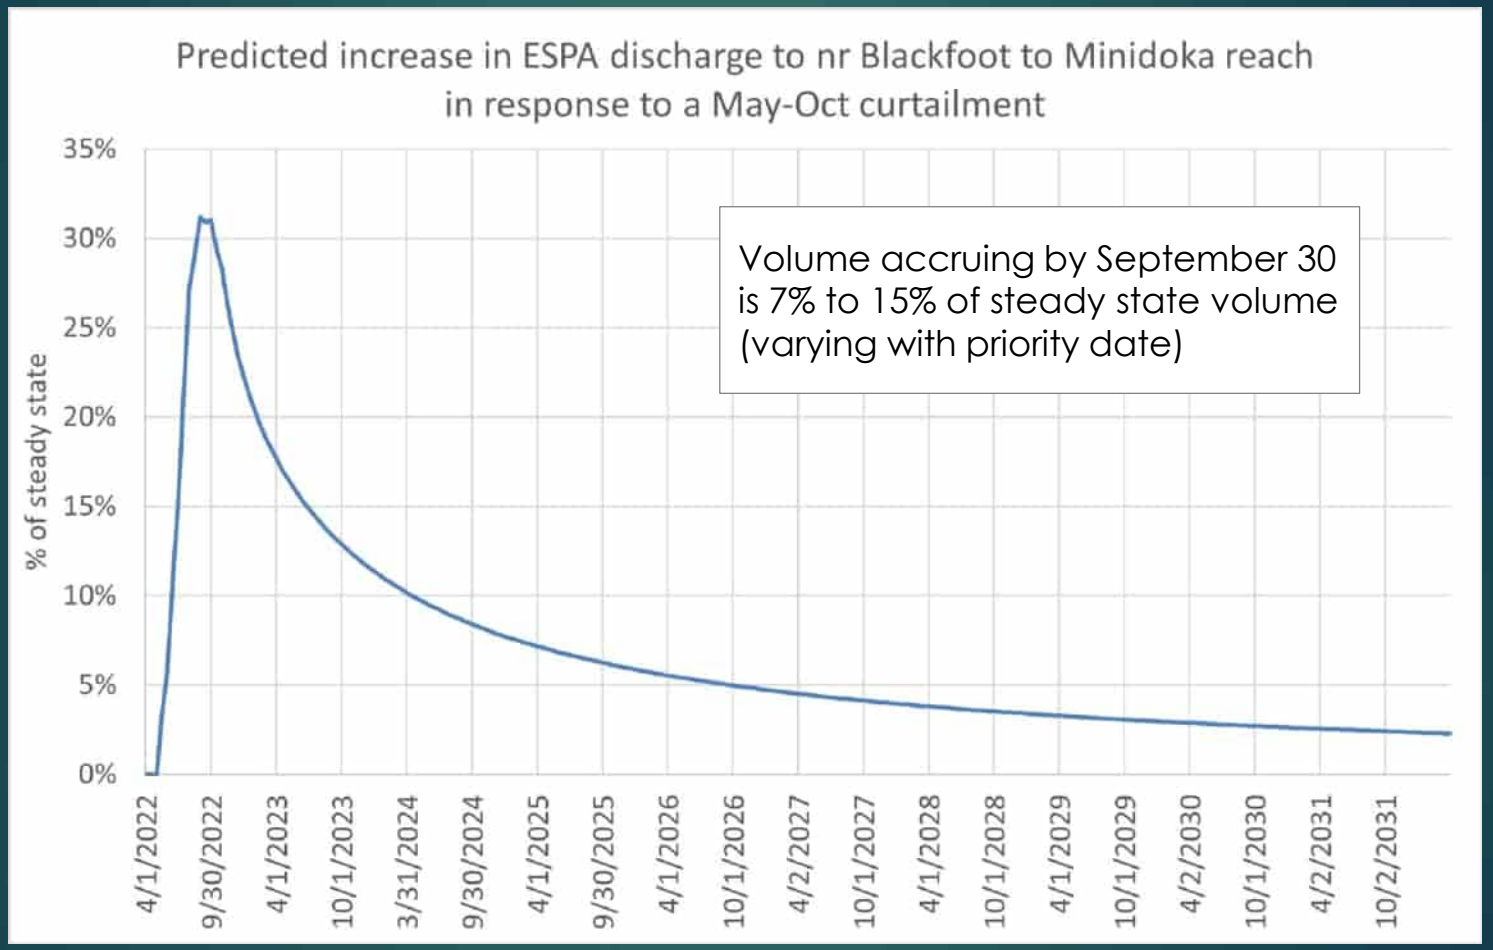
Steady state vs. transient model simulations

- Merriam-Webster definition of *steady state*
  - a state or condition of a system or process that does not change in time

- Steady state ESPAM simulation for calculation of curtailment priority date
  - Predicts long-term response to continuous curtailment of groundwater use at a constant rate for an infinite number of years
  - Result is a prediction of the long-term average annual impact of curtailment on the near Blackfoot to Minidoka reach
  - Curtailments ordered as prescribed in methodology order are not continuous or long-term
  - Groundwater use does not occur at a constant rate throughout the year



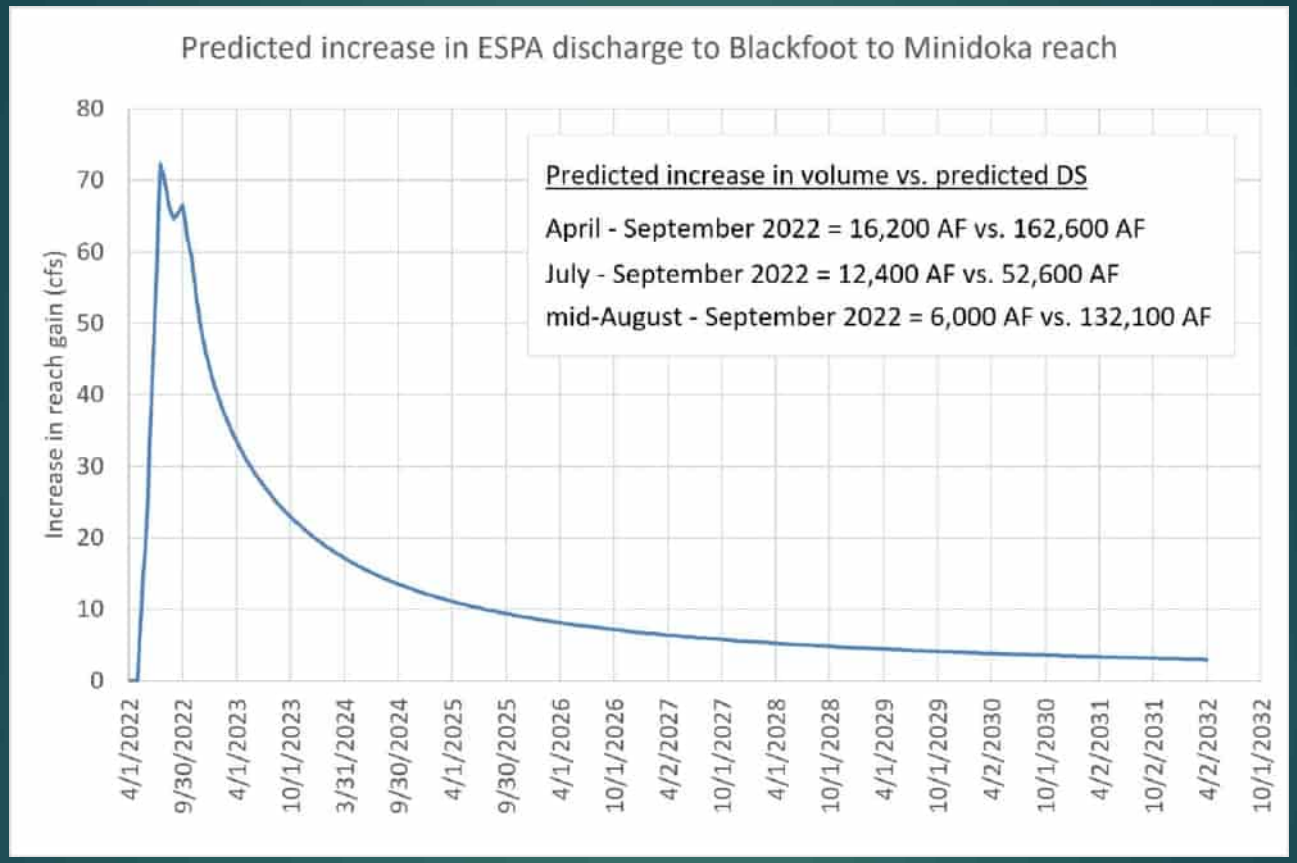
How long does it take to approach steady state conditions?



Steady state vs. transient model simulations

- Merriam-Webster definition of *transient*
  - passing especially quickly into and out of existence
- Transient ESPAM simulation for calculation of curtailment priority date
  - Predicts timing and magnitude of response to time-varying changes in aquifer stress resulting from short-term curtailment of groundwater use to address a predicted shortfall
  - Result is a prediction of the timing and magnitude of the response to time-varying curtailment of groundwater use

Steady state vs. transient model simulations

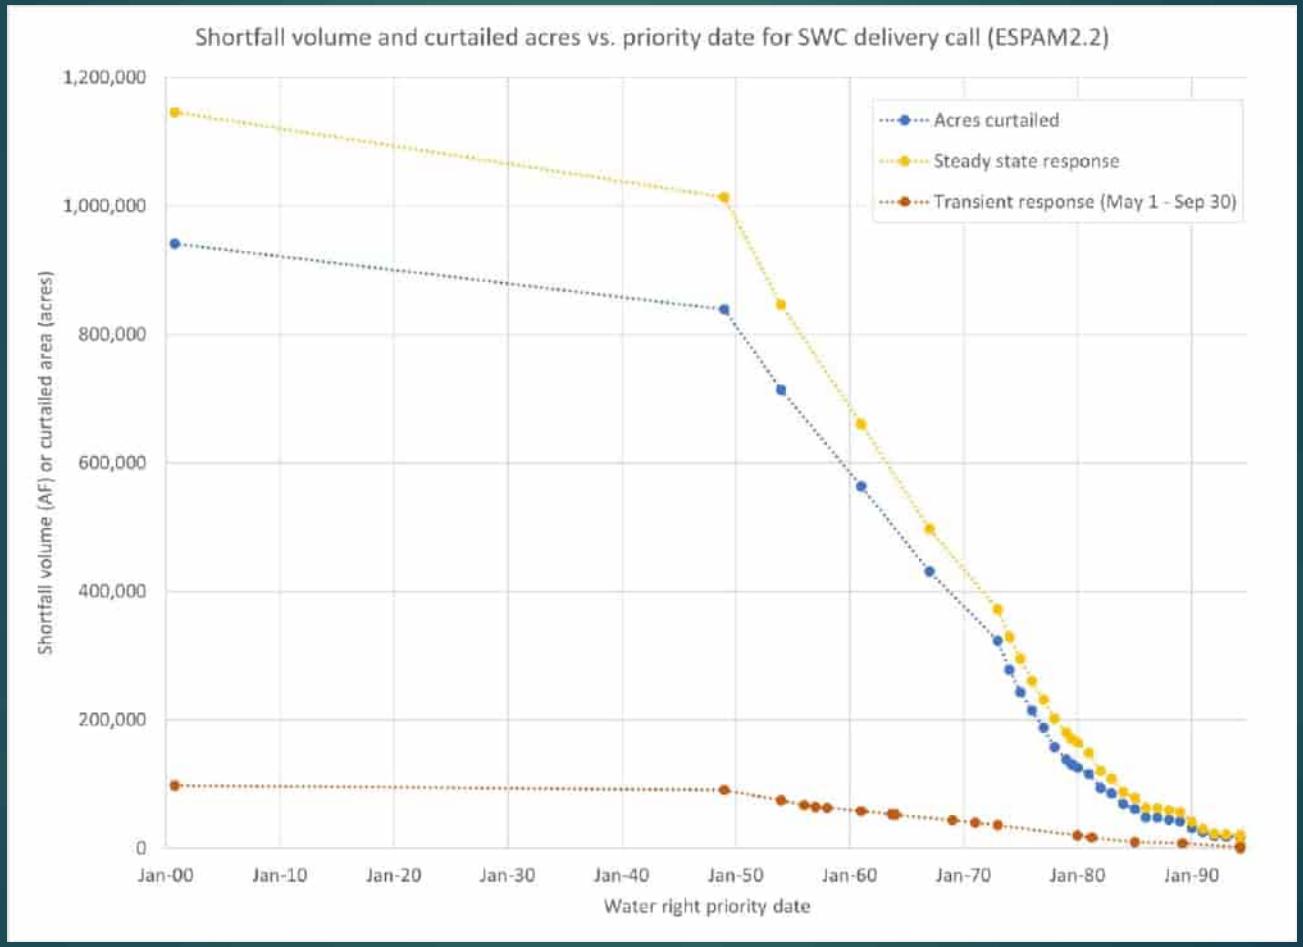


Steady state vs. transient model simulations

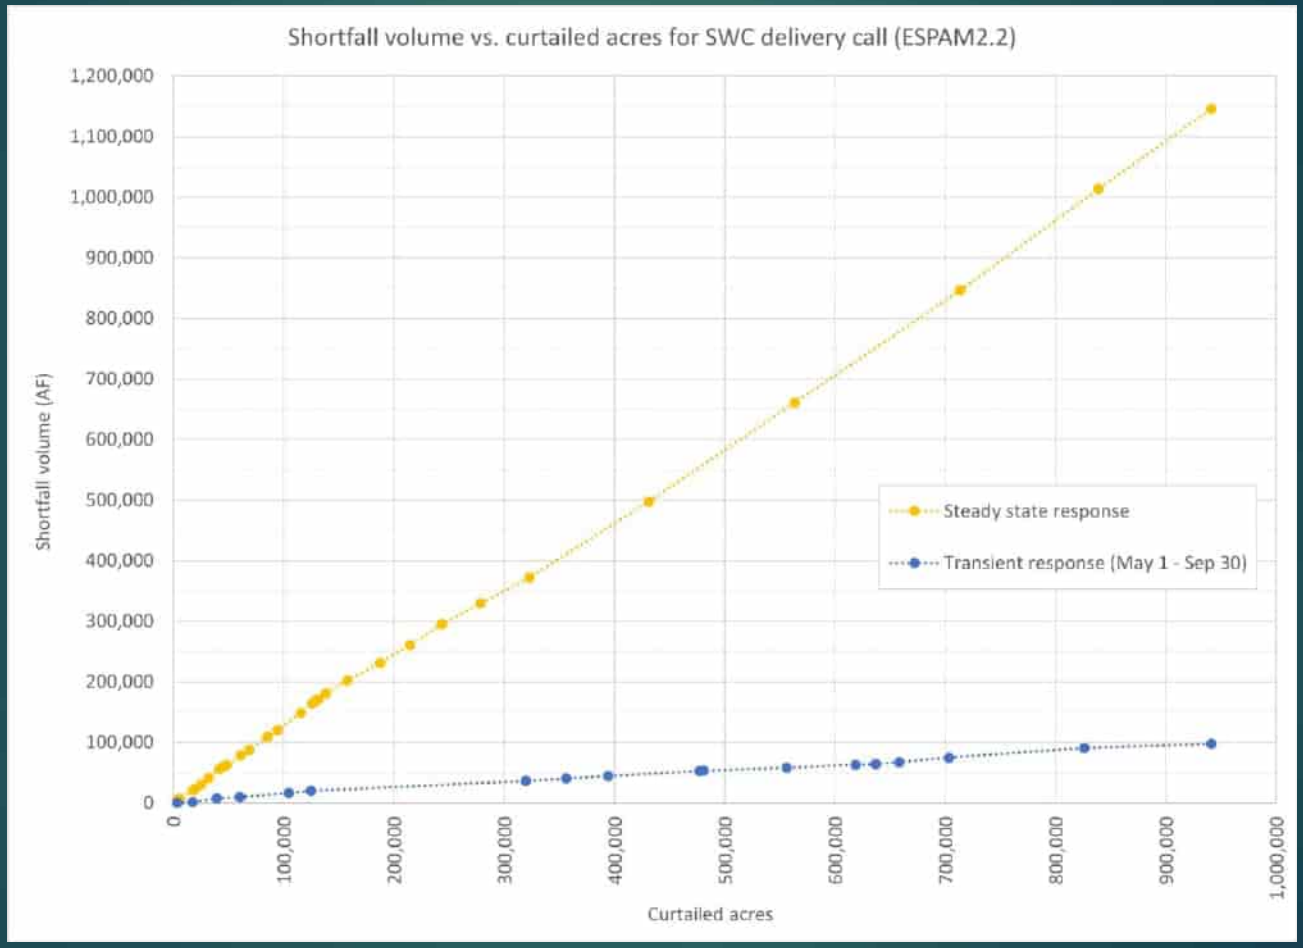
Transient simulation of curtailments ordered in 2022

- 2022 curtailments ordered
  - Curtailment priority dates were calculated based on steady state response at near Blackfoot to Minidoka
  - April 1 DS forecast of 162,600 AF → curtailment junior to December 25, 1979 beginning May
  - July 1 DS Forecast of 52,600 AF → curtailment reduced to junior to March 12, 1989 in July
  - Time of Need Forecast of 132,100 AF → curtailment increased to junior to March 25, 1981 in August
- Transient simulation of these curtailment dates was performed to compare volumes predicted to accrue to near Blackfoot to Minidoka during this season with the predicted DS volumes

Transient simulation of curtailments ordered in 2022

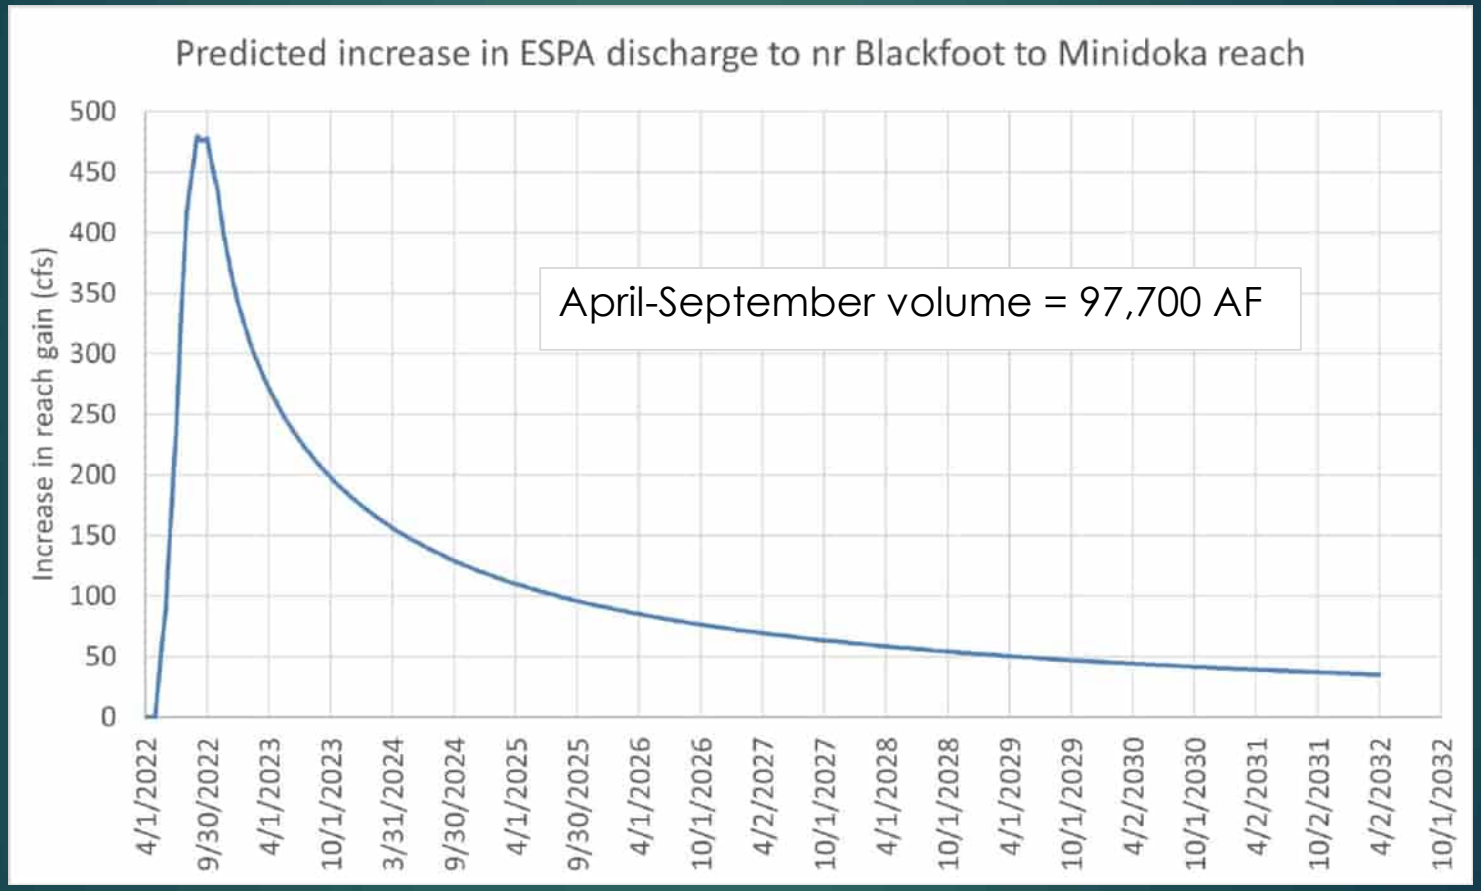


- Volume that would accrue from the ordered curtailments during the period of each shortfall is much less than the predicted shortfall
- Increases in reach gain would continue to accrue in future water years

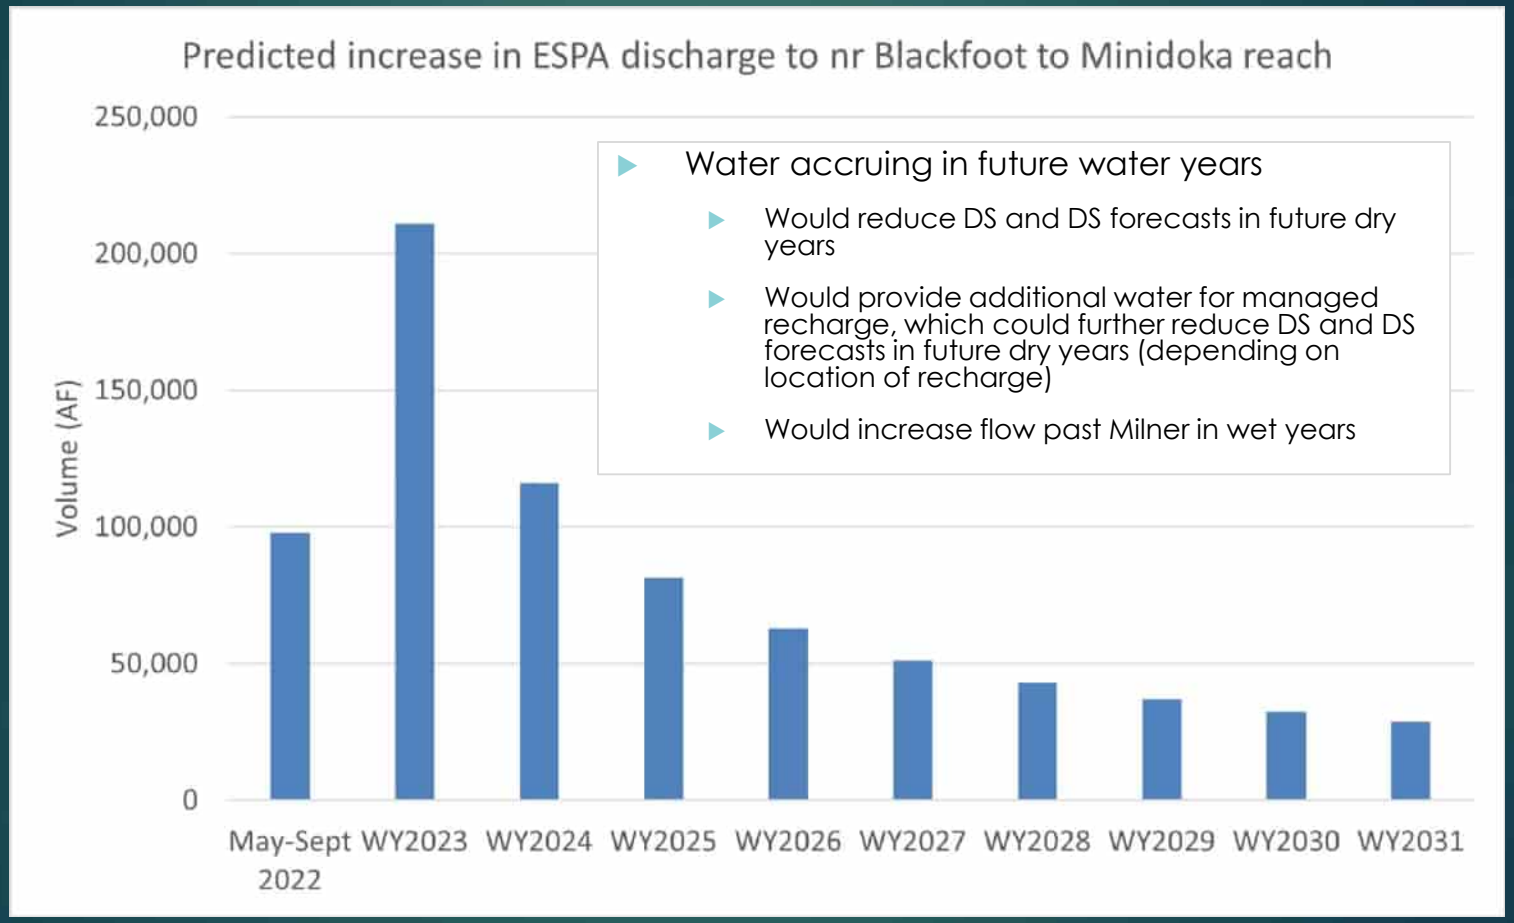


Assumptions for example transient model simulations

- Continue to use methods documented in "Curtailment Scenario" report (Sukow, 2021) https://research.idwr.idaho.gov/files/projects/espam/browse/ESPAM22_Reports/Scenarios/CurtScen22_FinalwApp.pdf
  - Use average monthly ET and precipitation from WY2009-WY2018 instead of average annual values
- Analysis of municipal curtailment continues to use methods described in 2015 IDWR staff memo for Rangen delivery call (Sukow, 2015) https://idwr.idaho.gov/wp-content/uploads/sites/2/legal/CM-MP-2014-007/CM-MP-2014-007-20150123-Staff-Memo-Cities-2nd.pdf
  - Five-year average pumping rates within ACGW are updated each year based on reported annual pumping volumes
- Curtailment for April forecast begins ~ May 1
- Curtailment priority date revision for July forecast goes into effect ~ July 16 if April DS > July DS
- Curtailment priority date revision for July forecast goes into effect ~ August 1 if April DS < July DS
- Curtailment priority date revision for Time of Need (mid-August) forecast goes into effect ~ September 1
- Target for transient calculation is a modeled benefit at near Blackfoot to Minidoka equal to DS volume accruing between DS forecast date and September 30
- Earliest curtailment priority date is junior to October 11, 1900 (TFCC and NSCC natural flow water rights)



Comparison of priority dates calculated for April DS forecasts (May 1 curtailment)



Comparison of priority dates calculated for April DS forecasts (May 1 curtailment)

Predicted response to May 1 curtailment of water rights junior to October 11, 1900

Predicted response to May 1 curtailment of water rights junior to October 11, 1900

Transient analyses for 2021 shortfall volumes

- April DS forecast = 40,500 AF
  - Curtail junior to **January 11, 1971** starting May 1
    - May 1 – Sep 30 predicted response = 40,500 AF
- July DS forecast = 170,000 AF
  - Increase curtailment to junior to **October 11, 1900** starting August 1
    - Jul 1 – Sep 30 predicted response = 44,400 AF
- Time of Need DS forecast = 142,700 AF
  - Maintain curtailment junior to **October 11, 1900**
    - Aug 16 – Sep 30 predicted response = 27,400 AF
- Carryover shortfall forecast = 64,600 AF
  - Curtail junior to **April 19, 1961** starting January 1
    - Jan 1 – Sep 30 predicted response = 64,700 AF

Transient analysis for 2021 carryover shortfall

- Calculation target is volume accruing between date of curtailment and September 30 of the next irrigation season
- Carryover shortfall forecast = 64,600 AF
  - Curtail junior to **April 19, 1961** starting January 1
    - Jan 1 – Sep 30 predicted response = 64,700 AF

Transient analyses for 2022 shortfall volumes

- April DS forecast = 162,600 AF
  - Curtail junior to **October 11, 1900** starting May 1
    - May 1 – Sep 30 predicted response = 97,700 AF
- July DS forecast = 52,600 AF
  - Decrease curtailment to junior to **March 13, 1981** starting July 16
    - Jul 1 – Sep 30 predicted response = 52,600 AF
- Time of Need DS forecast = 132,100 AF
  - Increase curtailment to junior to **October 11, 1900** starting September 1
    - Aug 16 – Sep 30 predicted response = 27,200 AF

Comparison of priority dates calculated using transient and steady state analyses

Forecast	Steady state date	Transient date	Steady state acres	Transient acres
April 1, 2021	1990	1/11/1971	~30,000	357,000
July 1, 2021	7/18/1979	10/11/1900	130,300	941,400
August 15, 2021	1981	10/11/1900	~110,000	941,400
Final net DS	1976	10/11/1900	~200,000	941,400
Carryover 2021	6/29/1985	4/19/1961	55,300	539,700
April 1, 2022	12/25/1979	10/11/1900	124,700	941,400
July 1, 2022	3/12/1989	3/31/1981	39,300	104,700
August 15, 2022	3/25/1981	10/11/1900	105,000	941,400

Range of priority dates using steady state simulations:
1976 – 1990 (30,000 to 200,000 acres)

Range of priority dates using transient simulations:
1900 – 1981 (105,000 to 940,000 acres)

Conclusions

- Steady state simulations are appropriate for evaluating the impact of aquifer stresses that have been applied for decades (i.e. groundwater pumping, continuous curtailment to same date every year)
- Transient simulations are appropriate to evaluate the impacts of aquifer stresses applied for short periods of time (i.e. short-term curtailments with varying priority dates)
- Steady state simulations of continuous curtailment do not simulate the short-term curtailments prescribed in the SWC methodology
- Transient simulations better simulate the short-term curtailments prescribed in the SWC methodology

Conclusions

- Short-term curtailments in response to in-season predictions of DS are inadequate to provide water during the time of need for several of the shortfall volumes predicted in 2021-2022
- Curtailments sufficient to provide water during the time of need would also provide water to reduce shortfalls in future dry years, but would result in additional flow past Milner in future wet years

IDAHO Department of Water Resources

IDAHO DEPARTMENT OF WATER RESOURCES

Proposed Modification of the Methodology For Determining Material Injury To Reasonable In-Season Demand and Reasonable Carryover: Project Efficiency

Presented by: Matt Anders

Date: 11/28/2022

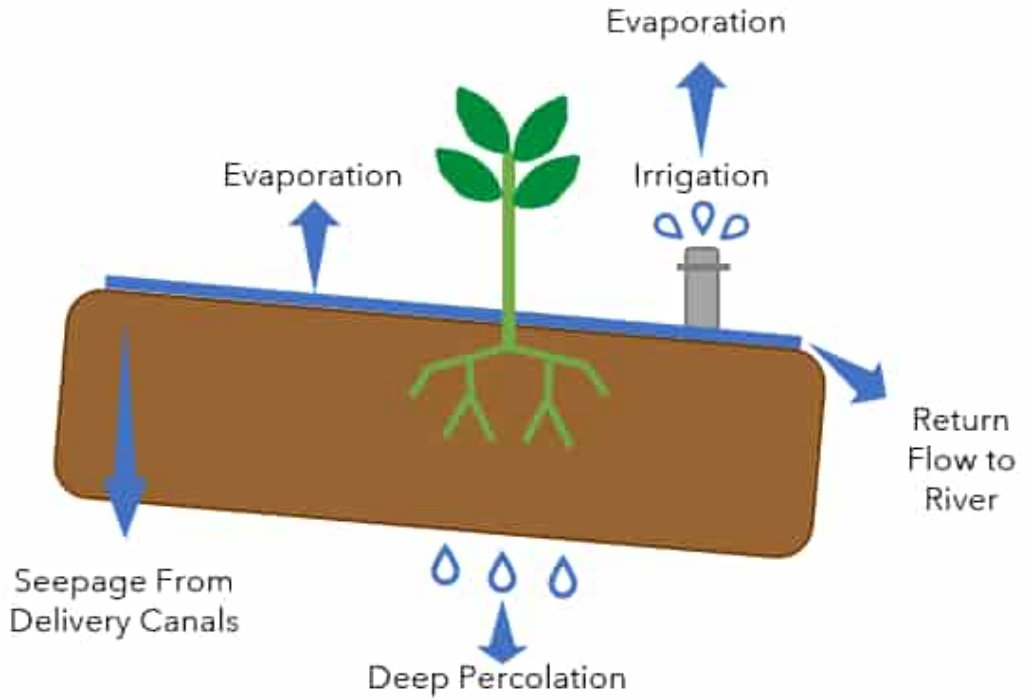
Elements of Shortfall Calculation – Project Efficiency

Milestone	Supply	Reasonable In-Season Demand (RISD)
April	Forecast Natural Flow (Apr-Oct) • Regression Equations Predicted Storage Allocation • Analogous Year or Years	Predicted Demand (Apr-Oct) • Historical Demand from Baseline Year (BLY)
July	Actual Diverted Natural Flow (Apr-June) Forecast Natural Flow (July-Oct) • Regression Equations Storage Allocation • Storage Report or Analogous Year	Crop Water Need (Apr-June) • ET • Precipitation • Project Efficiency Predicted Demand (July-Oct) • Historical Demand from Baseline Year (BLY)

Elements of Shortfall Calculation – Project Efficiency

Milestone	Supply	Reasonable In-Season Demand (RISD)
Time of Need	Actual Diverted Natural Flow (Apr-Time of Need) Forecast Natural Flow (Time of Need-Oct) • Natural Flow from Comparable Year Storage Allocation • Storage Report	Crop Water Need (Apr-Time of Need) • ET • Precipitation • Project Efficiency Predicted Demand (Time of Need-Oct) • Historical Demand from Baseline Year (BLY)
November	Actual Diverted Natural Flow (Apr-Oct) Storage Allocation • Storage Report	Crop Water Need (Apr-Oct) • ET • Precipitation • Project Efficiency

Methodology Reference



- Project Efficiency (Page 13 of Methodology)
  - Finding of Fact 30: Project efficiency is the ratio of total volumetric crop water need within a SWC entity's boundary and the total volume of water diverted by that entity to satisfy its crop needs. Implicit in this relationship are the components of seepage loss, on farm application losses, and system operational losses for which data is not obtainable by the Department. By utilizing project efficiency, the influence of the unknown components for which data is not obtainable can be captured and described without quantifying each of the components. Project efficiency is derived by dividing crop water need by total diversions:

$$E_p = \frac{CWN}{Q_D}$$

  - Where:
    - E_p = project efficiency
    - CWN = crop water need
    - Q_D = irrigation entity diversion of water specifically put to beneficial use for the growing of crops within the irrigation entity.

Examples of Losses Captured in Project Efficiency

- Seepage losses
  - Delivery canals
- On farm application losses
  - Evaporation from ground, sprinklers, and foliage
  - Deep percolation from saturated root zone
- System operational losses
  - Return flow to river

Methodology Reference

- Project Efficiency (Page 14 of Methodology)
  - Finding of Fact 32: Monthly project efficiencies will be computed for the entire irrigation season. Project efficiency varies from month-to-month during the season, and will typically be lower during the beginning and ending of the season. Monthly project efficiencies will be divided into actual monthly crop water need ("CWN") values to determine RISD during the year of evaluation.

$$RISD = \frac{CWN}{E_p}$$

  - Where:
    - RISD = reasonable in-season demand
    - CWN = crop water need
    - E_p = project efficiency

- Used in methodology calculation to calculate RISD for:
  - July
  - Time of Need
  - November

Methodology Reference

- Project Efficiency (Page 14 of Methodology)

Summary of Average PE Values for 2007-2014

Month	A&B	AFRD2	BID	Milner	Minidoka	NSCC	TFCC	Monthly Avg.
4	1.67	0.39	0.43	0.77	0.47	0.16	0.30	0.60
5	0.61	0.29	0.28	0.41	0.37	0.29	0.31	0.37
6	0.73	0.43	0.44	0.63	0.54	0.47	0.51	0.54
7	0.68	0.45	0.56	0.74	0.61	0.50	0.58	0.59
8	0.50	0.39	0.60	0.66	0.53	0.32	0.44	0.49
9	0.41	0.26	0.48	0.56	0.44	0.21	0.26	0.38
10	0.14	0.26	0.14	0.15	0.14	0.05	0.04	0.13
Season Avg.	0.68	0.35	0.42	0.56	0.44	0.29	0.35	

- Updates since 2015:
  - Fixed error in the 2000-2010 crop percentages used in crop water need
  - Updated crop water need for 2014

Calculating Project Efficiency: 2022

- Average Project Efficiency is calculated for each SWC member and for each month

$$\text{Project Efficiency} = \frac{\text{Crop Water Need (AF)}}{\text{Demand (AF)}}$$

  - Exclude values greater than 2 standard deviations by month from the 2001-2021 dataset (highlighted in blue)
  - Average the values from the most recent 8-year period (2014-2021)
  - Example: A&B for 2022

Month	2014	2015	2016	2017	2018	2019	2020	2021	Average
4	1.13	0.43	1.44	0.66	1.21	1.07	0.61	0.69	0.91
5	0.49	0.35	0.70	0.55	0.40	0.20	0.45	0.49	0.46
6	0.67	0.75	0.64	0.63	0.60	0.62	0.35	0.61	0.64
7	0.77	0.66	0.79	0.79	0.78	0.70	0.73	0.72	0.74
8	0.48	0.50	0.53	0.61	0.56	0.59	0.56	0.53	0.54
9	0.45	0.46	0.23	0.39	0.50	0.39	0.47	0.48	0.42
10	0.24	0.20	0.03	0.35	0.12	0.38	0.28	0.04	0.21

Average Project Efficiency Values for 2014-2021

Month	A&B	AFRD2	BID	Milner	Minidoka	NSCC	TFCC	Monthly Avg.
4	0.91	0.34	0.44	0.83	0.53	0.23	0.31	0.51
5	0.46	0.20	0.30	0.33	0.38	0.21	0.29	0.31
6	0.64	0.38	0.46	0.53	0.57	0.39	0.51	0.50
7	0.74	0.43	0.53	0.62	0.66	0.46	0.58	0.58
8	0.54	0.41	0.47	0.52	0.59	0.44	0.48	0.49
9	0.42	0.29	0.36	0.42	0.43	0.33	0.29	0.36
10	0.21	0.07	0.10	0.14	0.14	0.06	0.05	0.11
Season Avg.	0.56	0.30	0.38	0.49	0.47	0.30	0.36	

Applying Project Efficiency: 2022

- Reasonable In-Season Demand (RISD)

$$RISD = \frac{CWN}{E_p}$$

  - Where:
    - RISD = reasonable in-season demand
    - CWN = crop water need
    - E_p = project efficiency

- Example: A&B for 2022

Month	Monthly Crop Water Need (AF)	Average Project Efficiency 2014-2021	Monthly RISD (AF)
4	2,028	0.91	2,241
5	3,378	0.46	7,397
6	8,528	0.64	13,256
7	11,058	0.74	14,918
8	3,381	0.54	6,214
9		0.42	
10		0.21	

Change in Average Project Efficiency Values Since 2014 Order

Month	A&B	AFRD2	BID	Milner	Minidoka	NSCC	TFCC	Monthly Avg.
4	-0.77	-0.05	0.00	0.06	0.05	0.08	0.02	-0.09
5	-0.15	-0.09	0.01	-0.07	0.01	-0.09	-0.03	-0.06

7	0.06	-0.02	-0.03	-0.11	0.04	-0.04	0.00	-0.01
8	0.04	0.02	-0.13	-0.13	0.07	0.12	0.05	0.00
9	0.01	0.02	-0.13	-0.14	-0.01	0.12	0.03	-0.01
10	0.06	-0.18	-0.04	-0.01	0.00	0.02	0.01	-0.02
Season Avg.	-0.12	-0.05	-0.04	-0.07	0.03	0.02	0.01	

- Reasons for change since 2014 Order
  - Fixed error in the 2000-2010 crop percentages
  - Updated crop water need for 2014
  - Changes in project efficiency

Possible Changes to Project Efficiency

- To calculate Crop Water Need for each SWC member:
  - Currently using an average of the Project Efficiency for most recent 8 years.
  - Update to use an average of the Project Efficiency for most recent 15 years.

Possible Change to Project Efficiency

- Project Efficiency for most recent 15 years (2007-2021).

Month	A&B	AFRD2	BID	Milner	Minidoka	NSCC	TFCC	Monthly Avg.

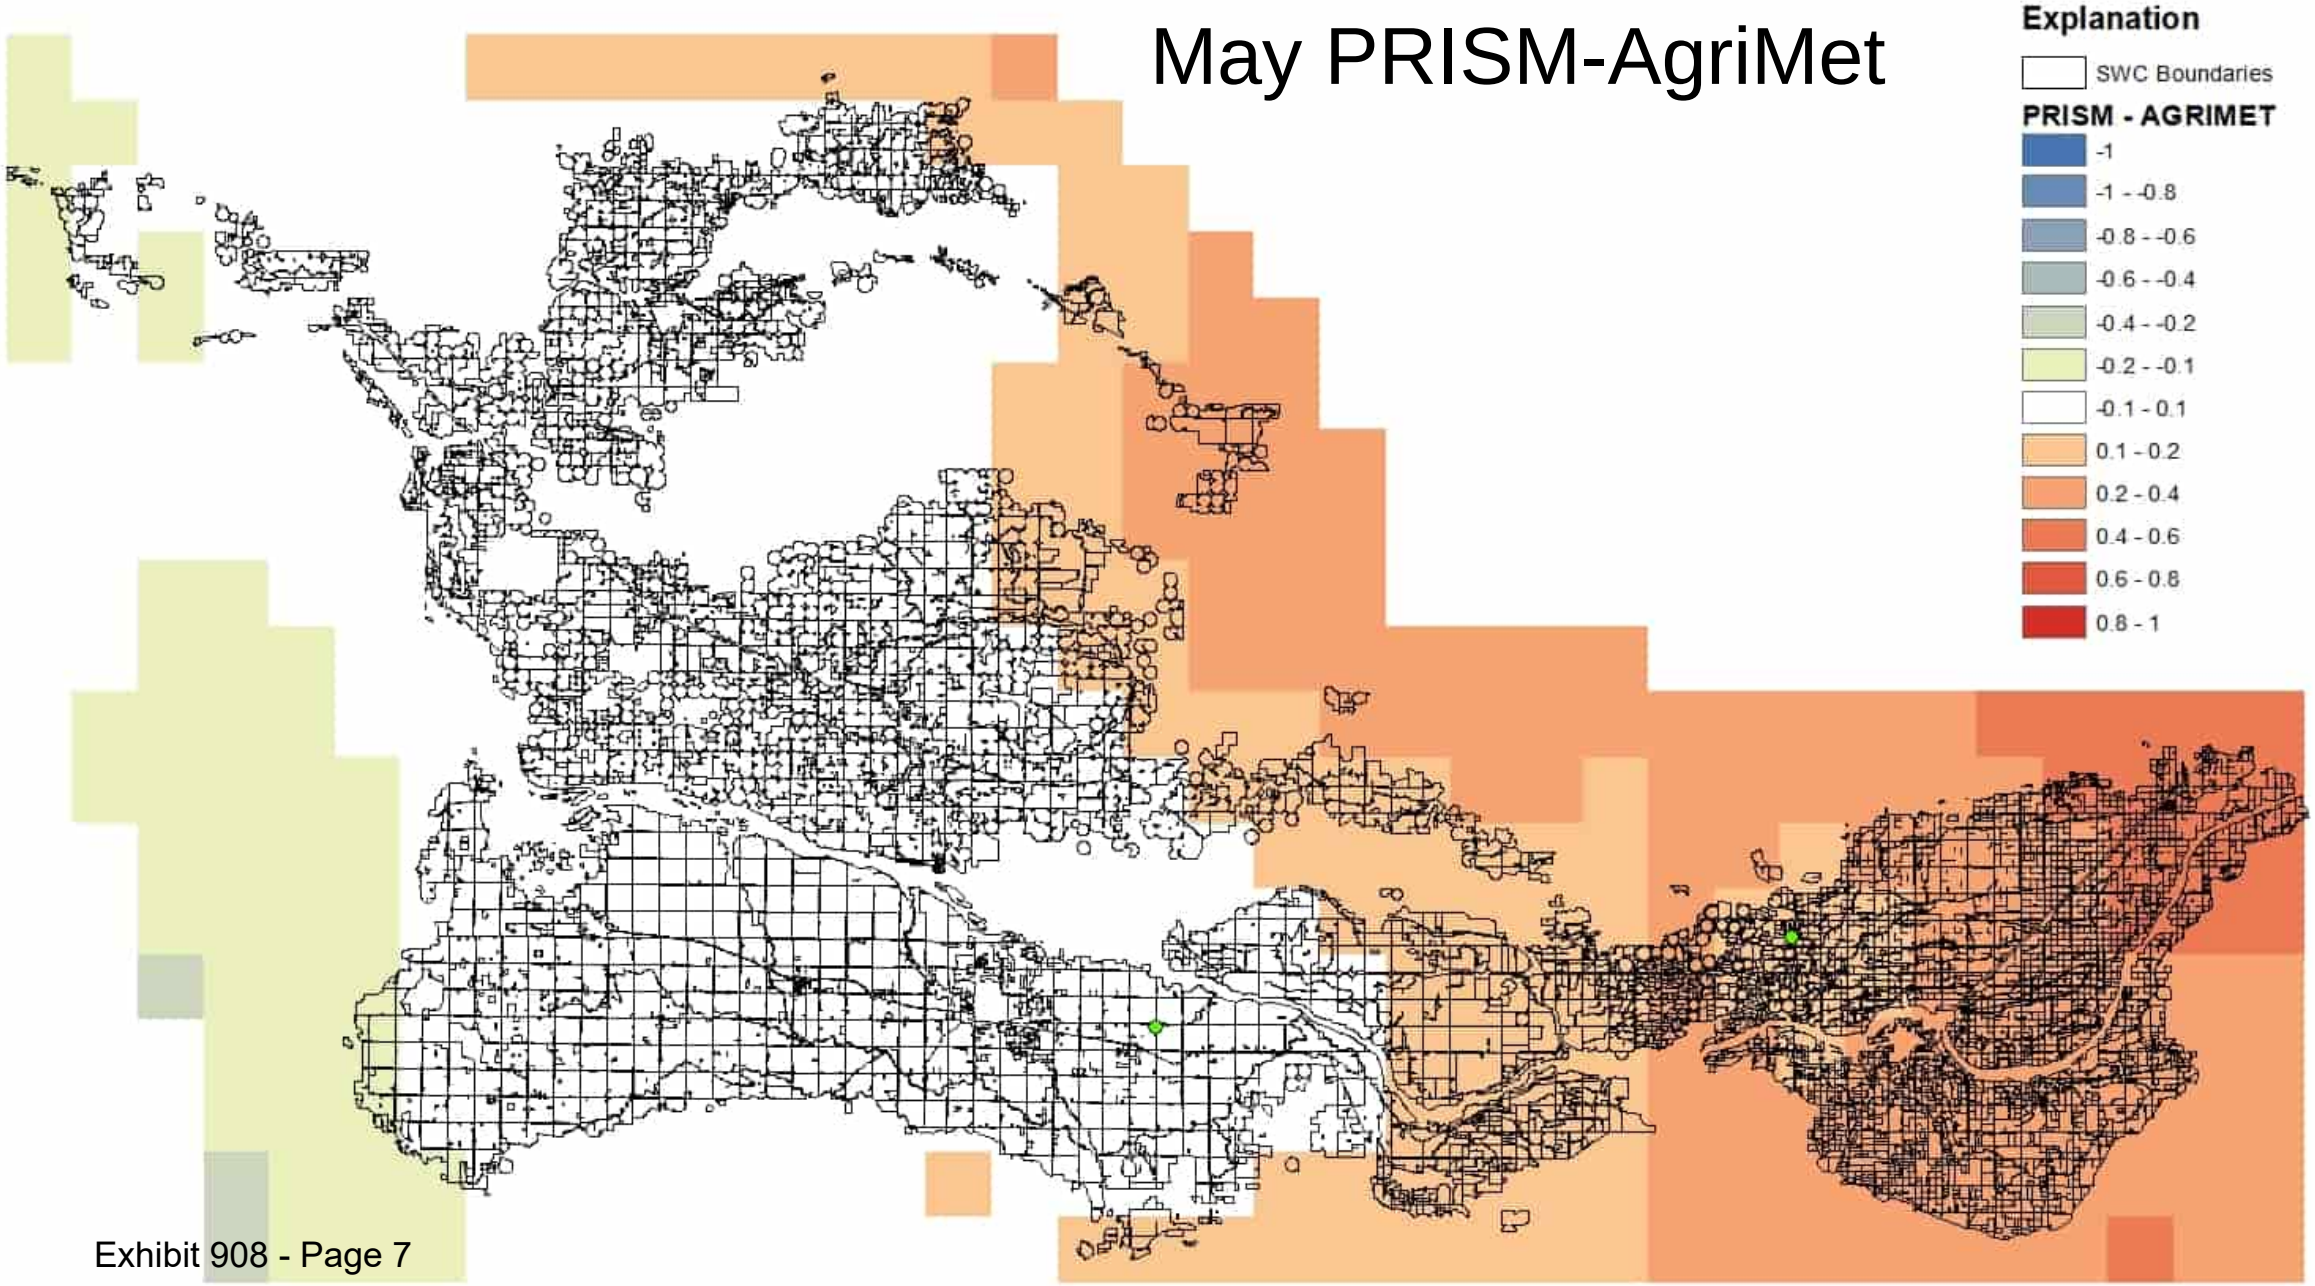
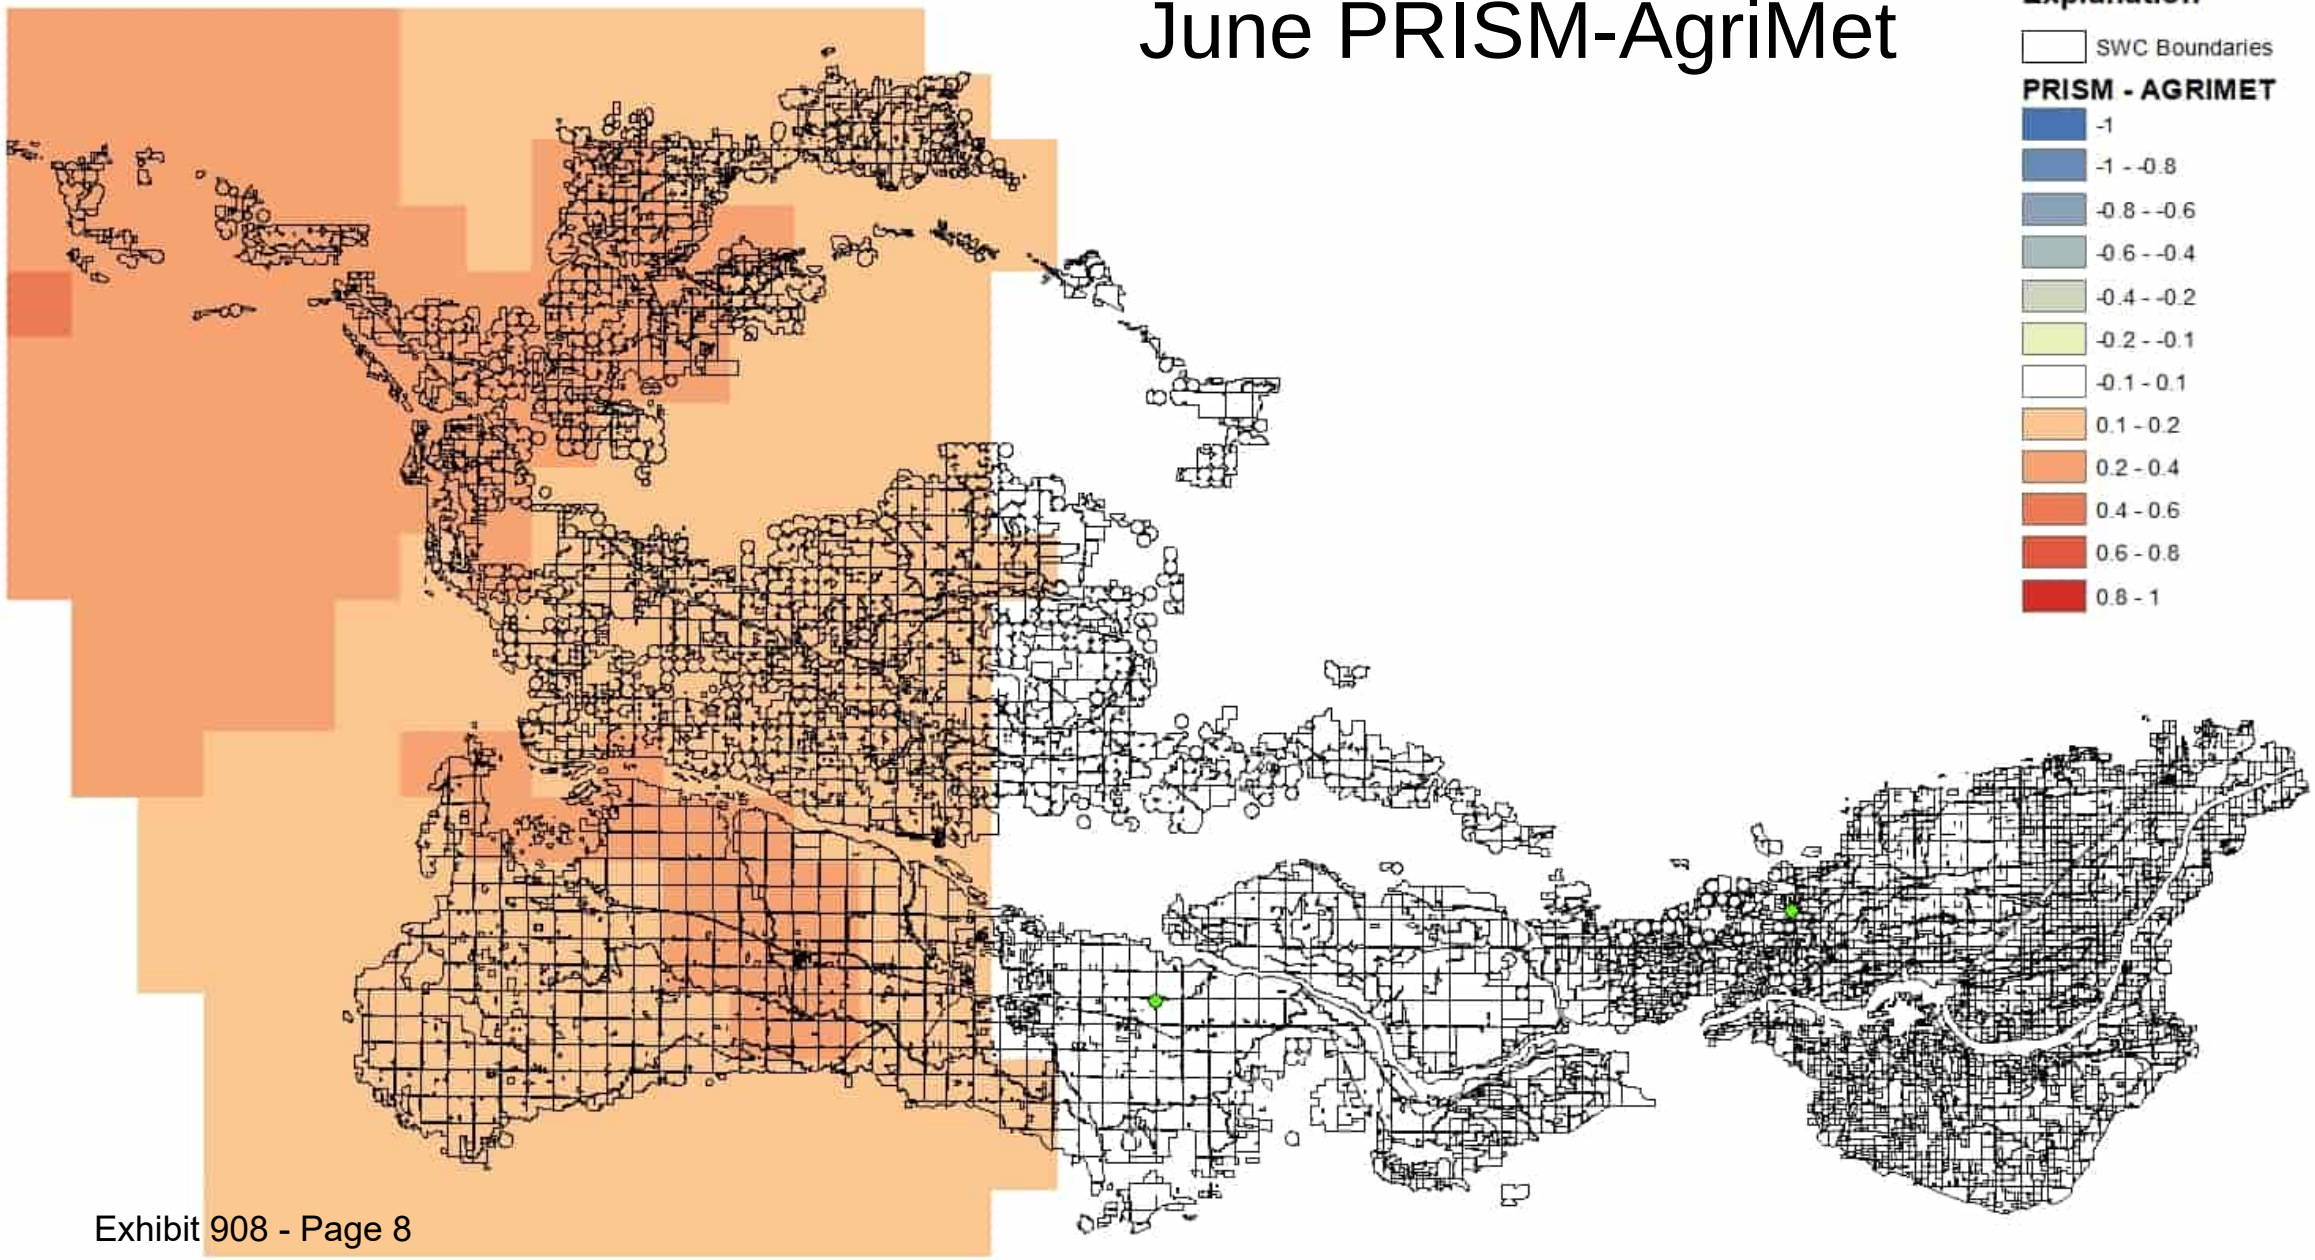
PRISM – AgriMet Difference Analysis for 2021

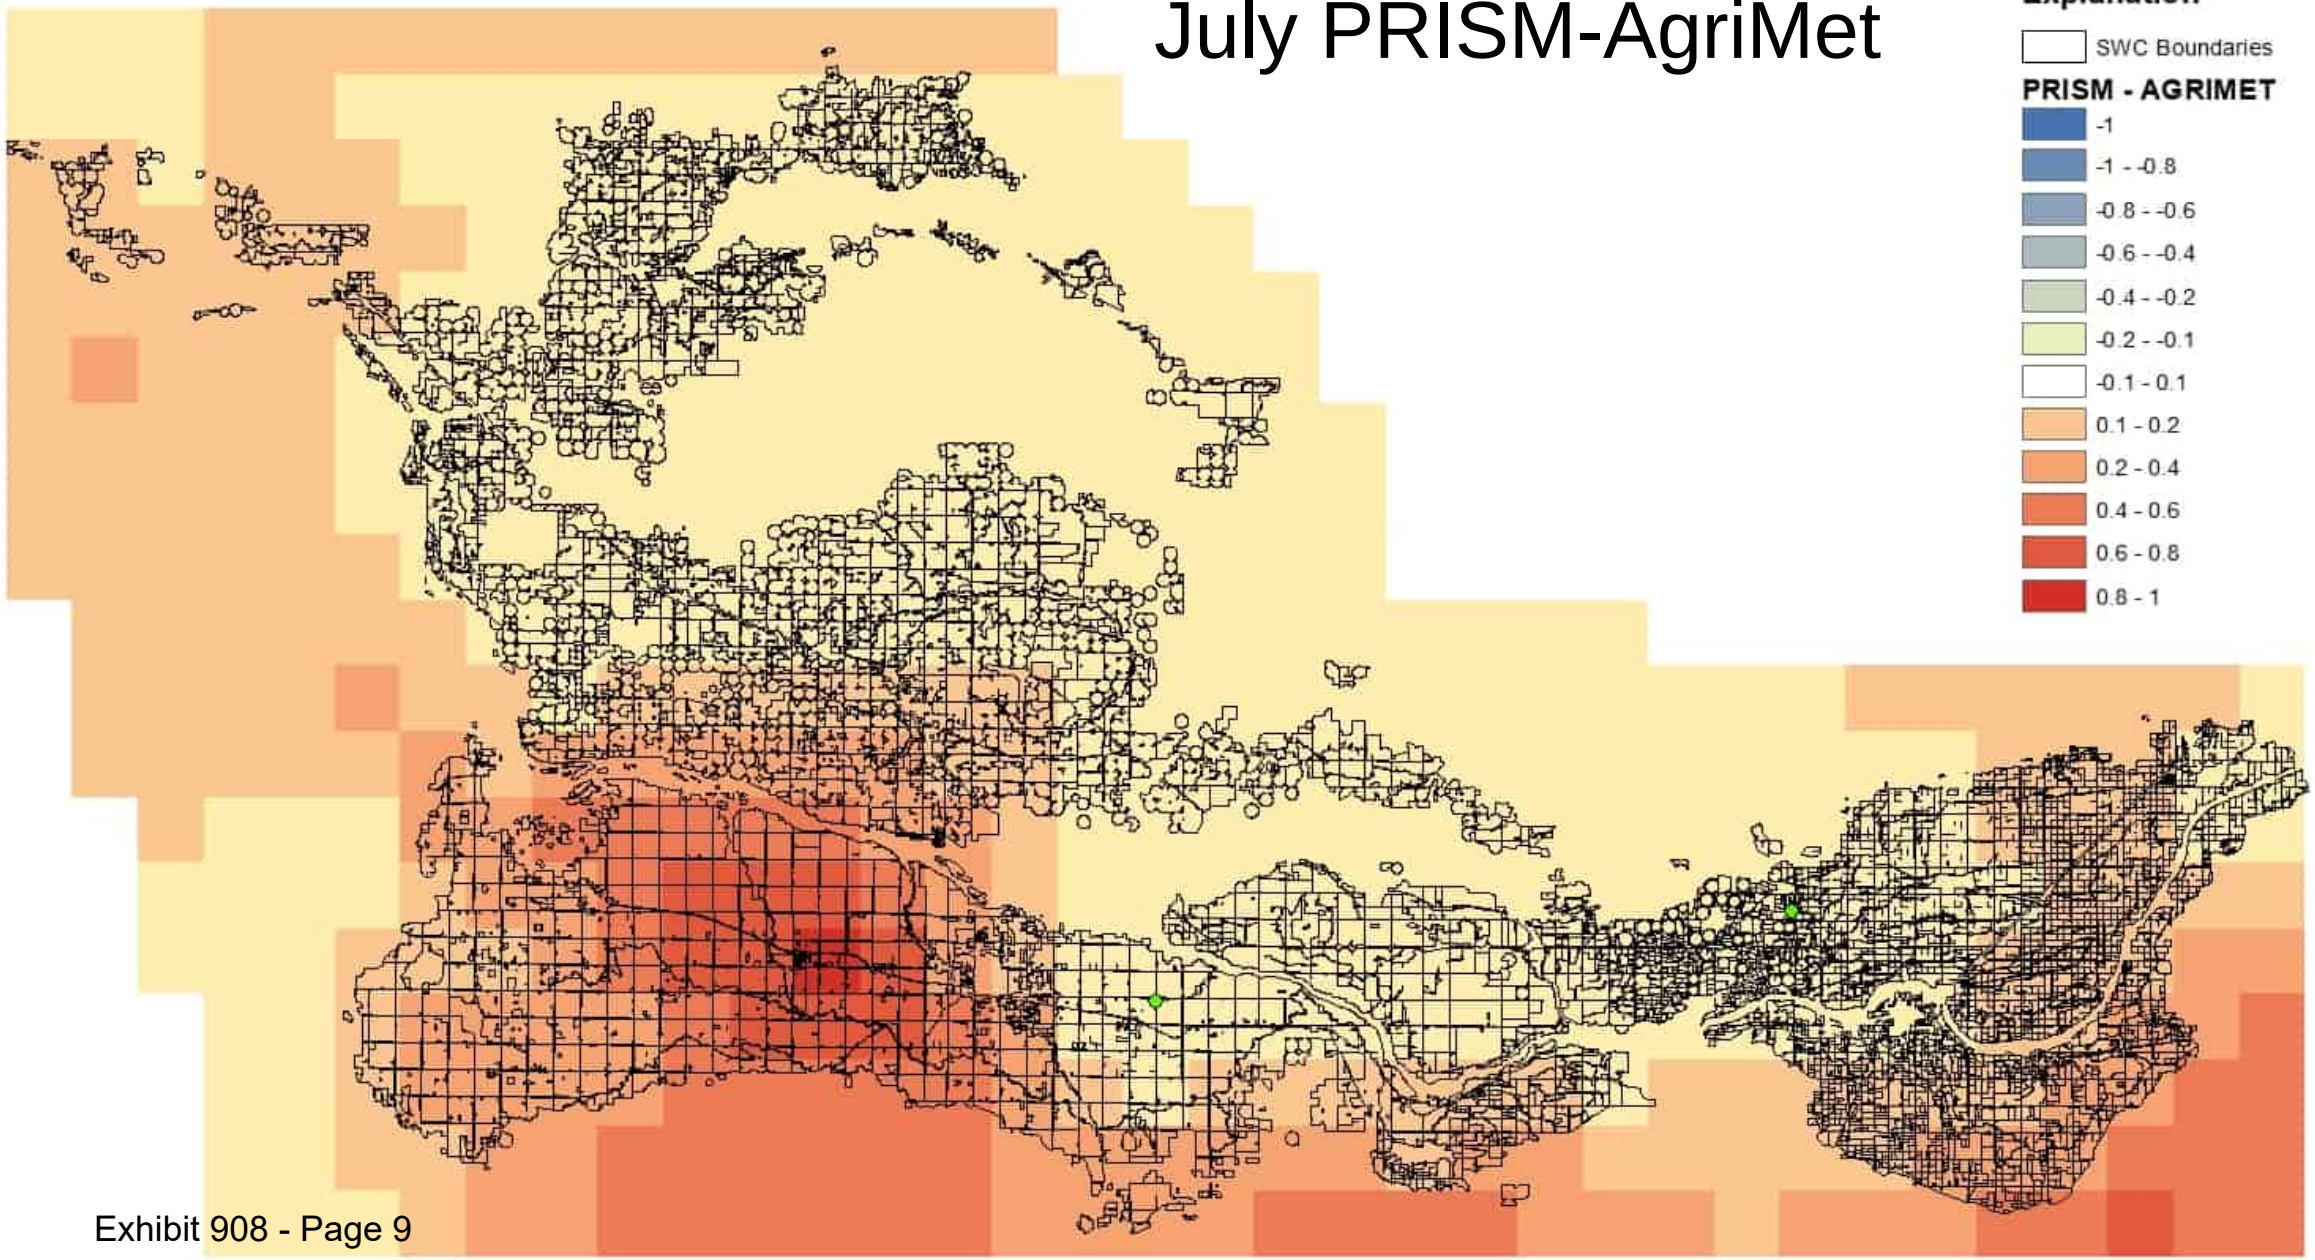


PRISM – AgriMet Difference Analysis for 2021

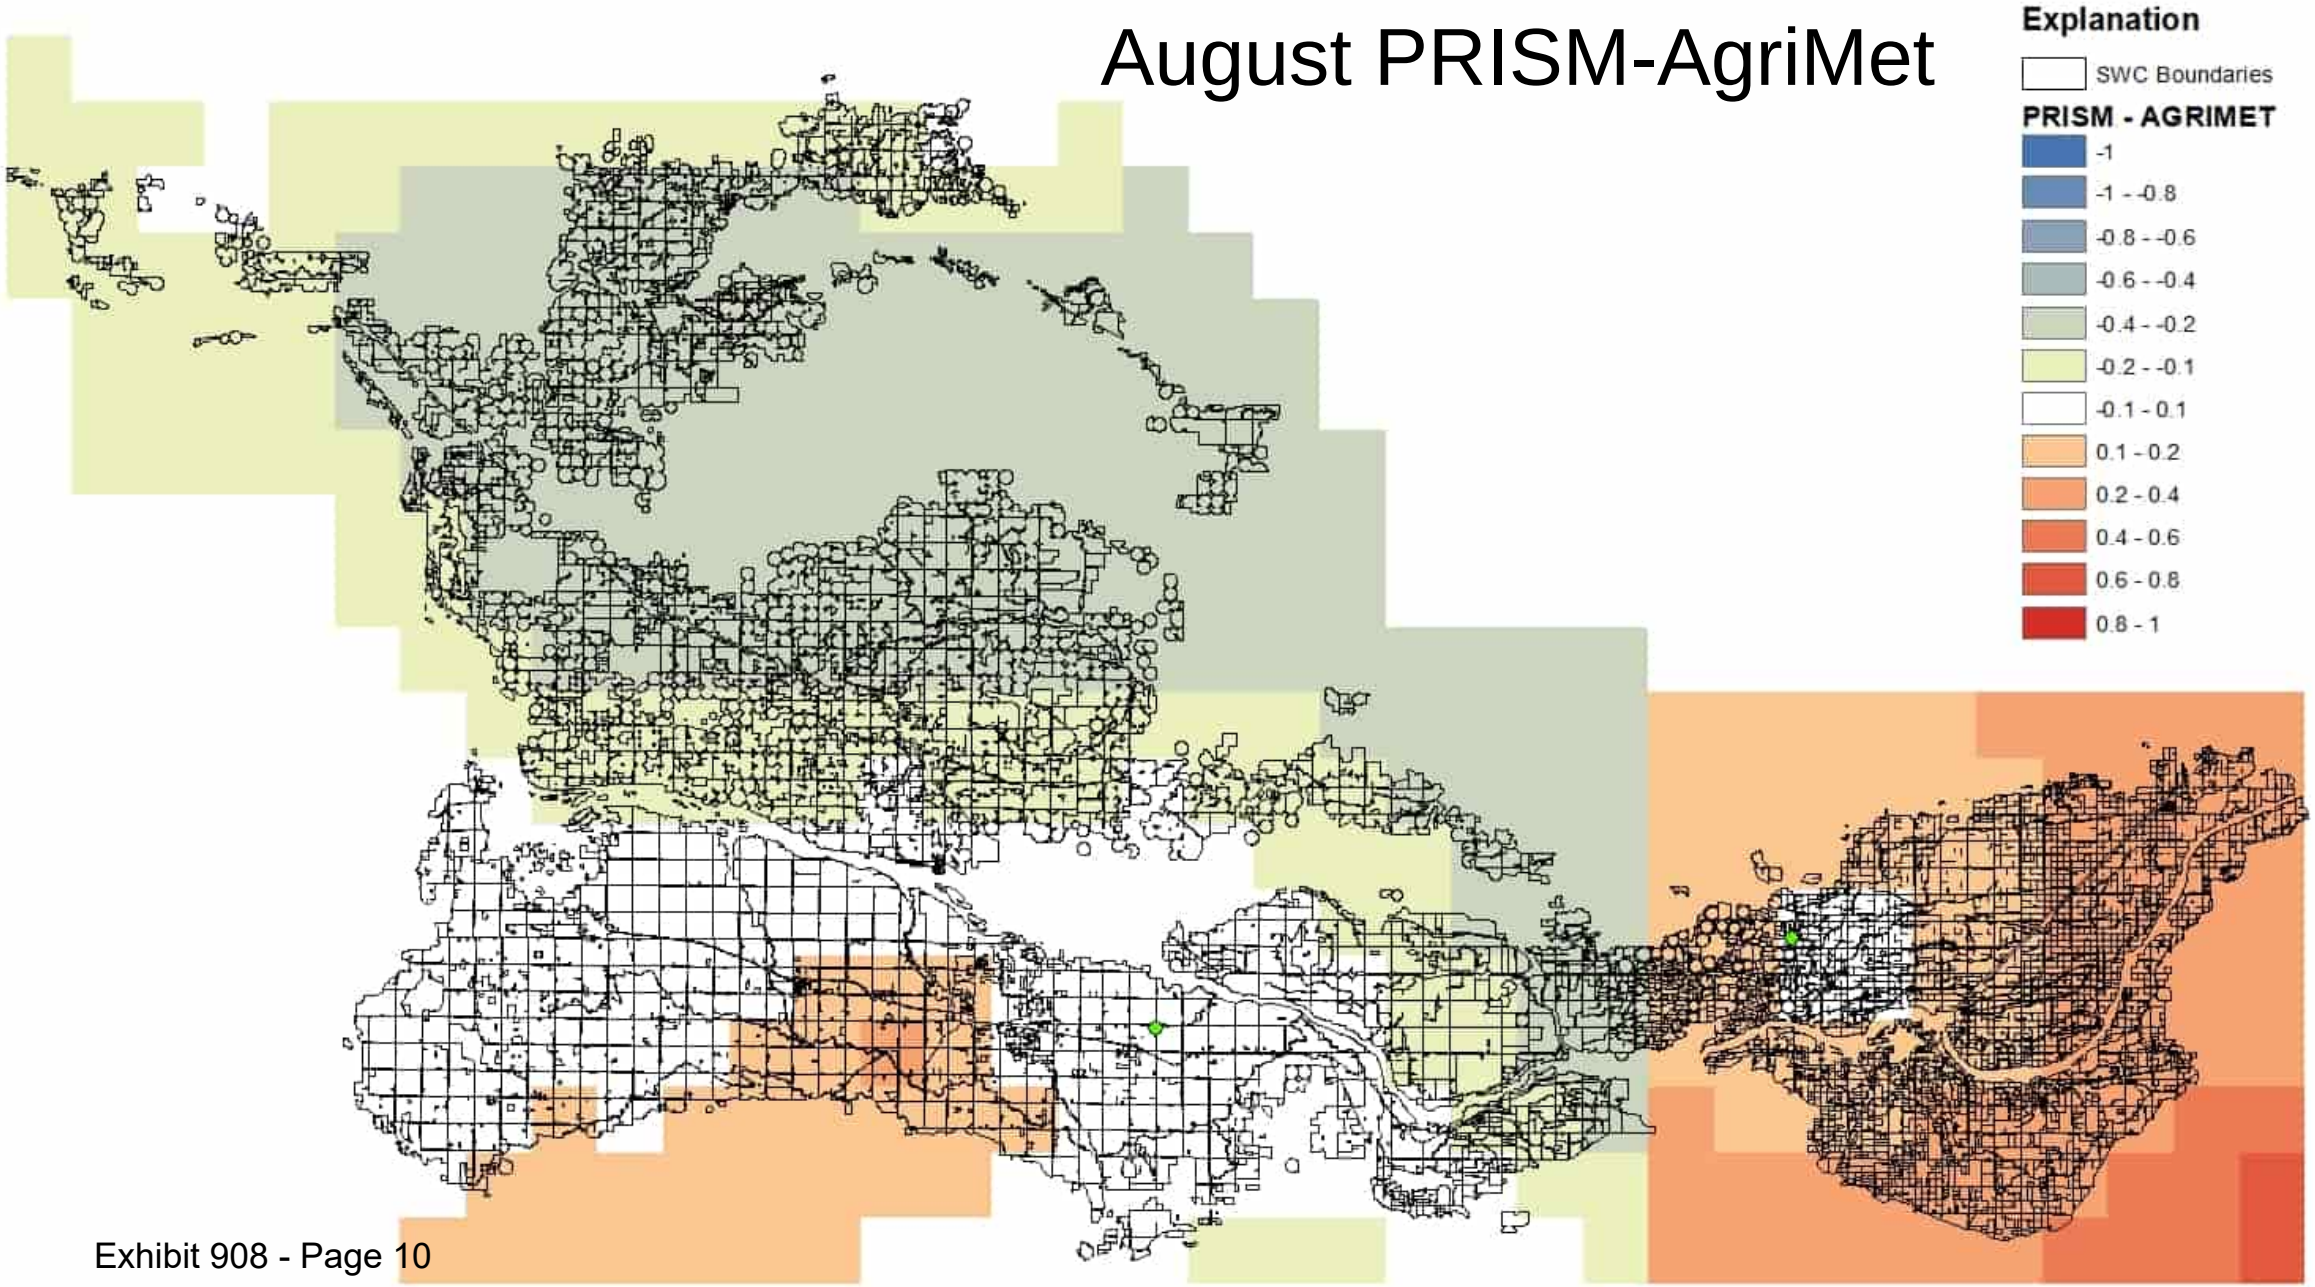
- Value (in inches) represent the difference between Effective precipitation from PRISM minus Effective Precipitation from AgriMet
- Same Effective precipitation method was used for both methods
- Twin Falls AgriMet was included for:
  - TFCC, AFRD2, NSCC, Milner
- Rupert AgriMet was included for:
  - A&B, Burley, MID
- Negative value in the graph below indicates Agrimet Effective precipitation was higher and would therefore decrease Crop Water Need more than PRISM for that month
- White background indicates the difference was between -0.1 and 0.1 inches



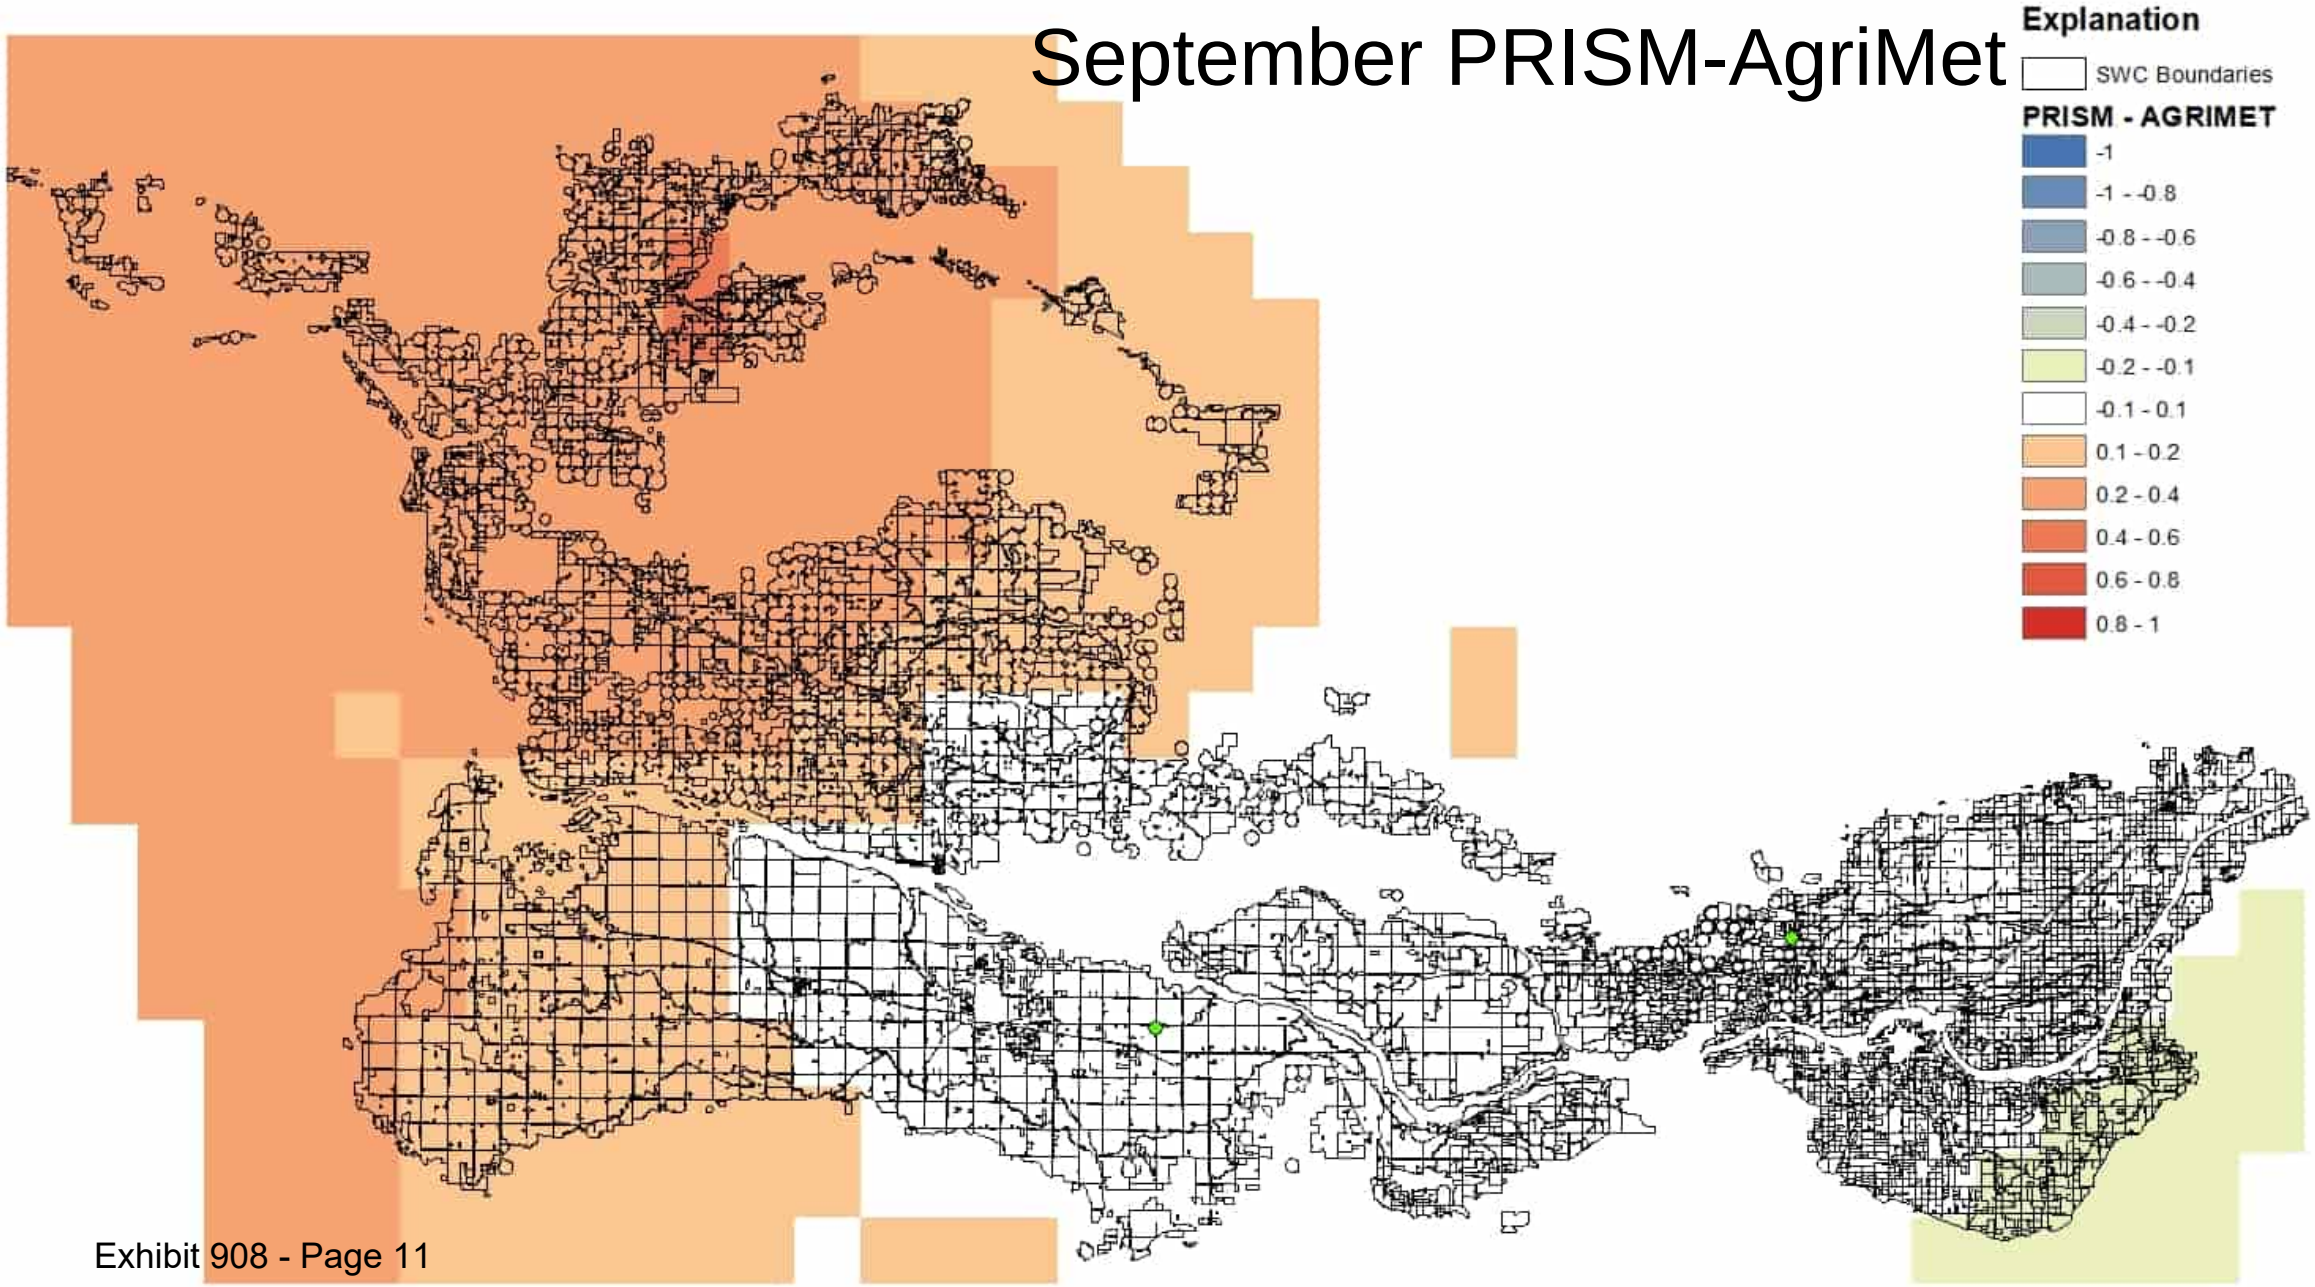
April PRISM-AgriMet



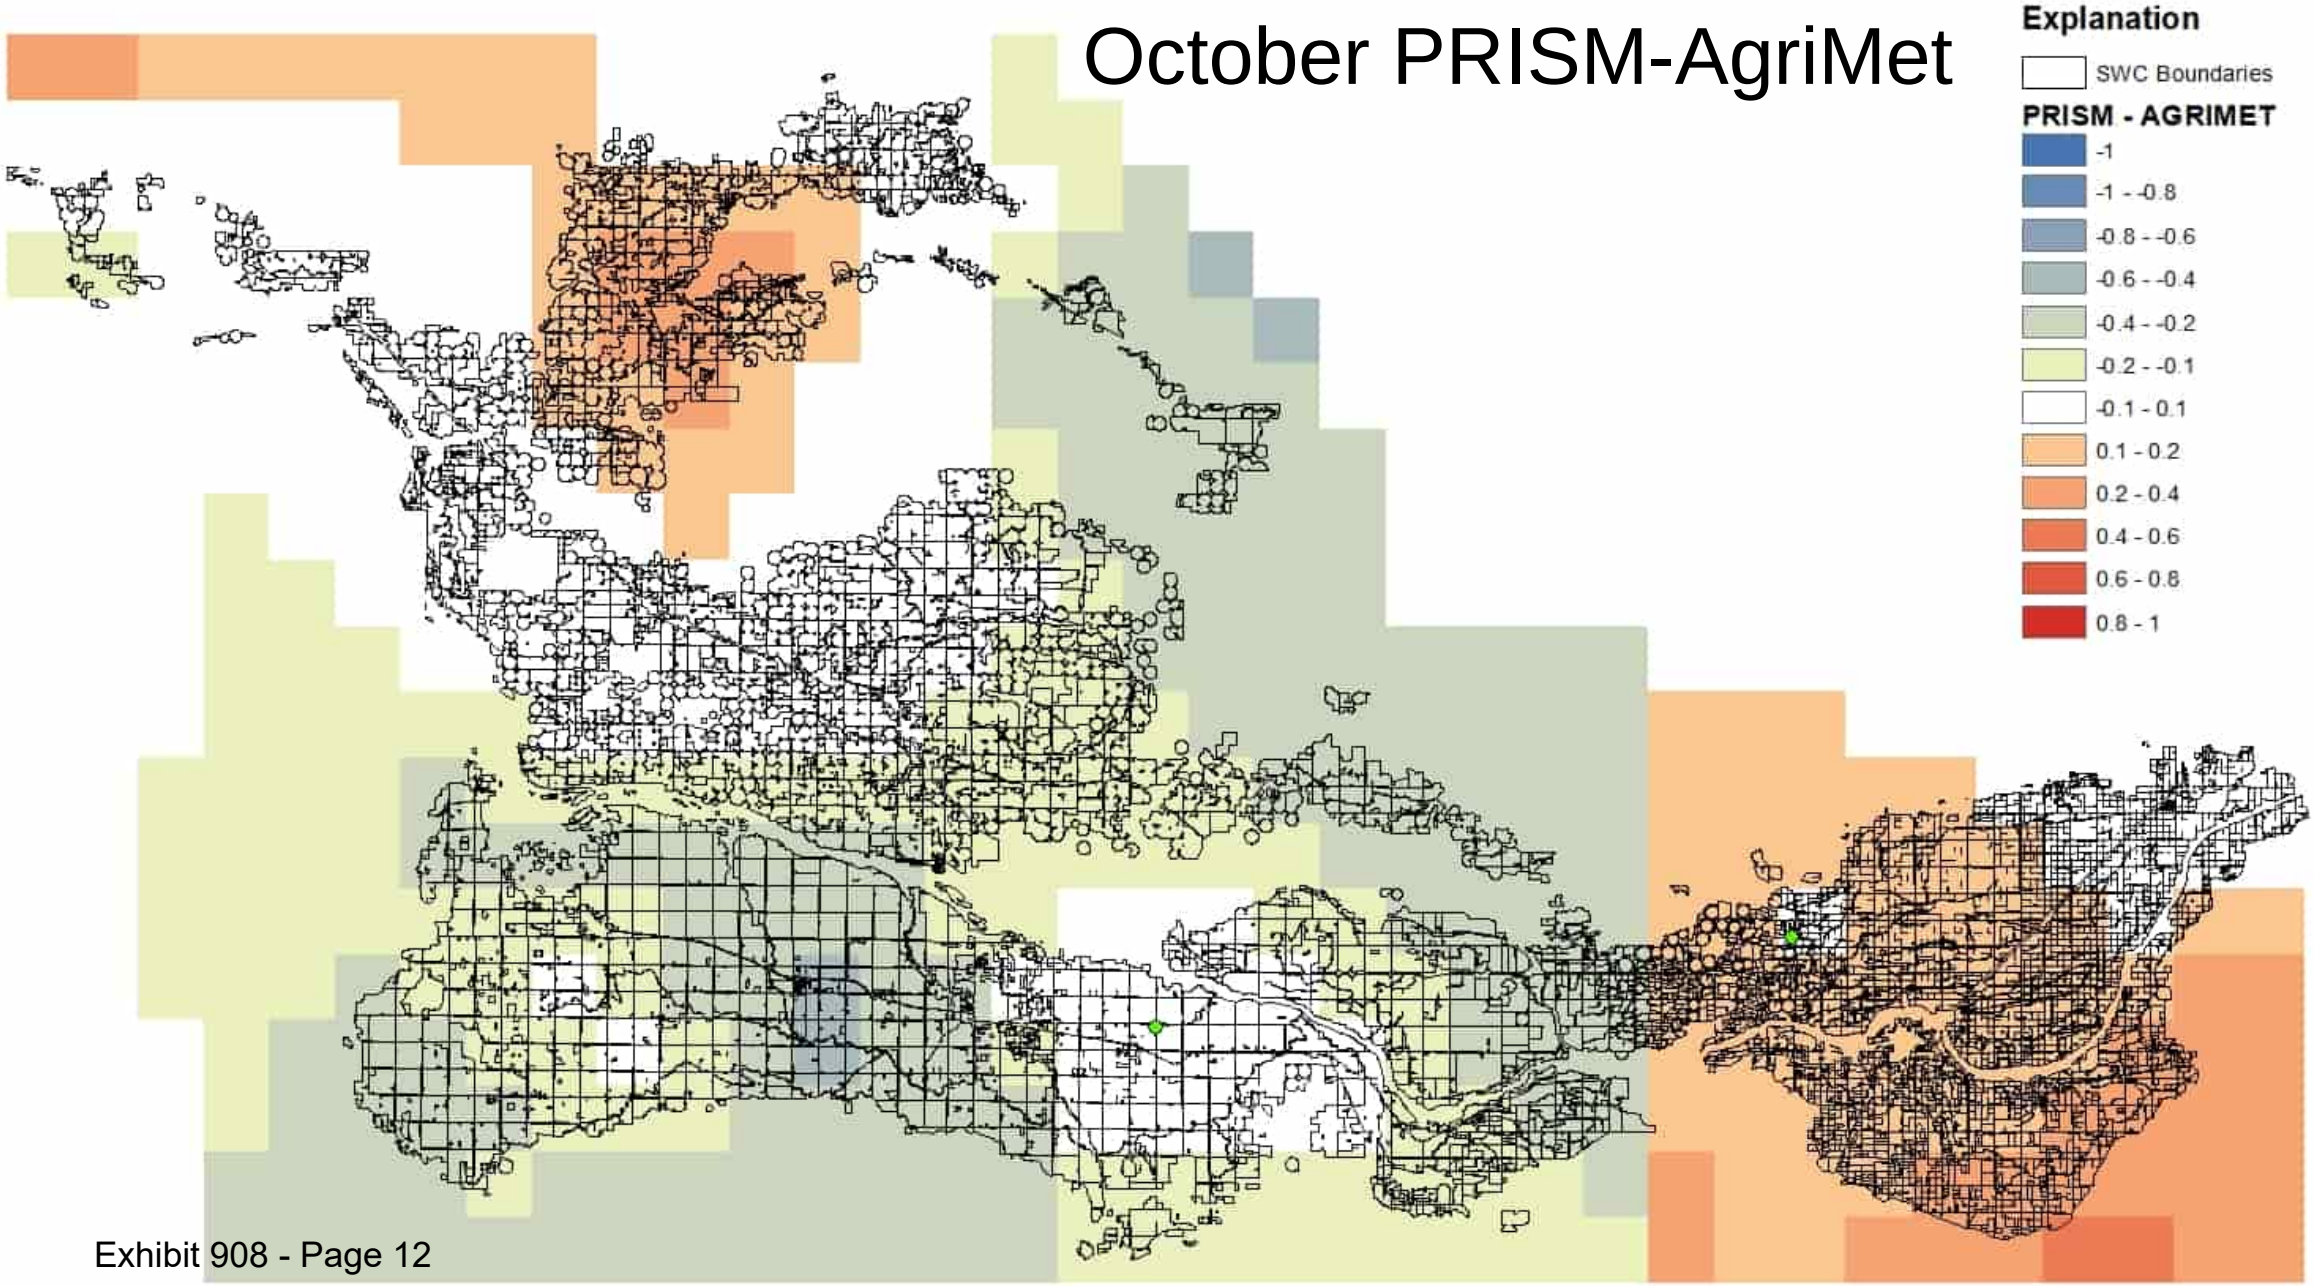
May PRISM-AgriMet



June PRISM-AgriMet



July PRISM-AgriMet



August PRISM-AgriMet

September PRISM-AgriMet

October PRISM-AgriMet

SWC Irrigated Acres

Current Method Crop Water Need

$CWN_{crop} = (ET_{crop}$- Effective Precipitation) * $Acres_{crop}$

- AgriMet ET
- Daily data from Rupert & Twin Falls stations.

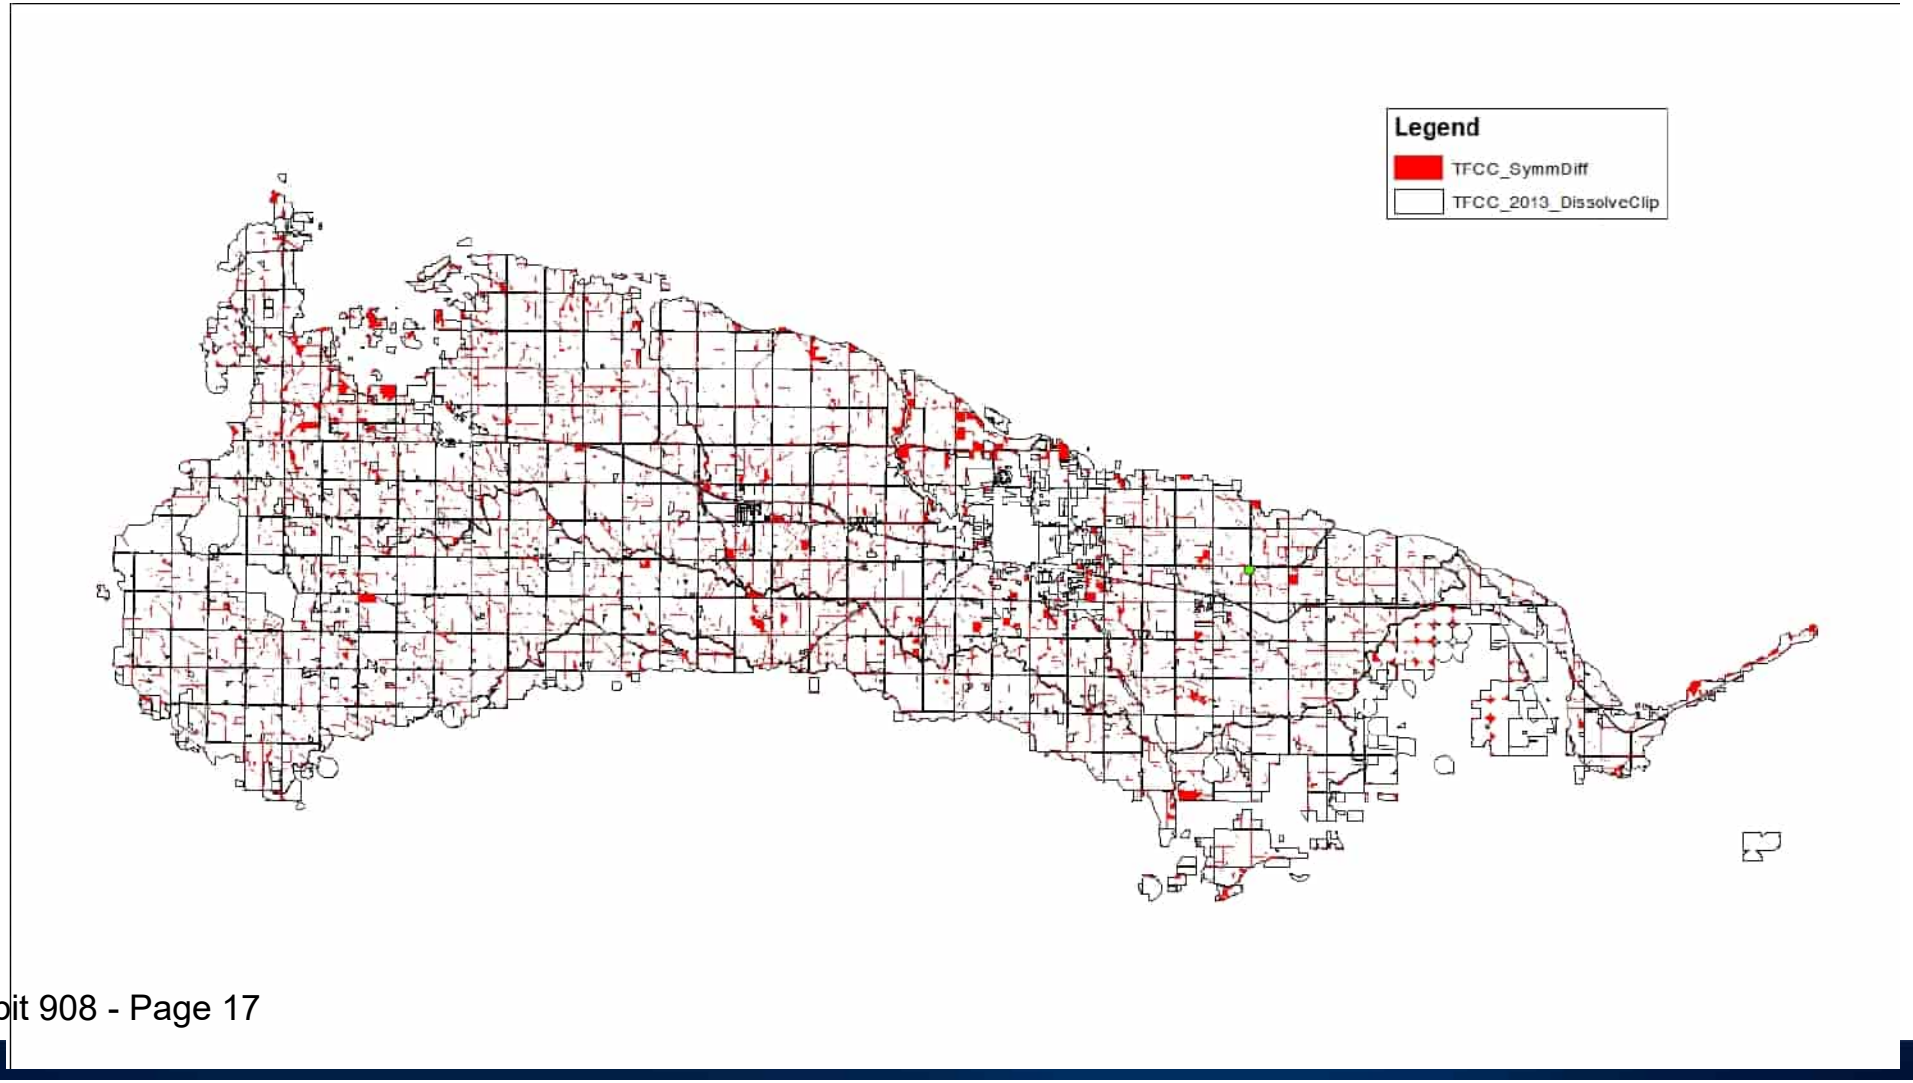
- AgriMet Precipitation
- Daily data from Rupert & Twin Falls stations.
- Calculate monthly effective precipitation.

- USDA Crop Data Layer (CDL)
- Remove data speckling and assign the majority crop in each polygon.
- Remove non-irrigated land from CDL using the IDWR Irrigated Lands Dataset.
- Clip CDL to SWC service areas.
- Determine the 3-year average crop mix percentage
- Acres of Each Crop = Crop Mix % * Acres From Methodology

Proposed Method NRT METRIC Crop Water Need

CWN = (ET - Effective Precipitation) * Acres

- NRT METRIC
- Remove non-irrigated land
- Normalize “ET – Effective Precipitation” to AF/Acre for each SWC member



- Irrigated acres from methodology

- Oregon State University Prism Precipitation
- Calculate monthly effective precipitation

SWC Irrigated Acres

SWC Member	Created by SWC or IDWR PPU	Date of Shapefile	Shapefile Acres	CDL Processing Acres (2021)	NRT METRIC Processing Acres (2021)	Methodology Acres

Example – Non-Irrigated Acres Removed From TFCC

Methodology Reference

- Irrigated Acres (Page 35 of Methodology)
  - Step 1:
    - Department staff will review submitted shapefiles and modify them as necessary to ensure that:
      - (1) the total acreage count does not exceed the decreed number of acres;
      - (2) all of the irrigated land is located within the decreed place of use; and
      - (3) acres are not counted more than once due to overlapping polygons within a shapefile or between shapefiles submitted by different SWC members.
    - Because the SWC members can best determine the irrigated acres within their service area, the SWC should be responsible for submitting the information to the Department.
      - If this information is not timely submitted, the Department will determine the total irrigated acres based upon past cropping patterns and current satellite and/or aerial imagery.
      - If a SWC member fails or refuses to identify the number of irrigated acres within its service area by April 1, the Department will be cautious about recognizing acres as being irrigated if there is uncertainty about whether the acres are or will be irrigated during the upcoming irrigation season.

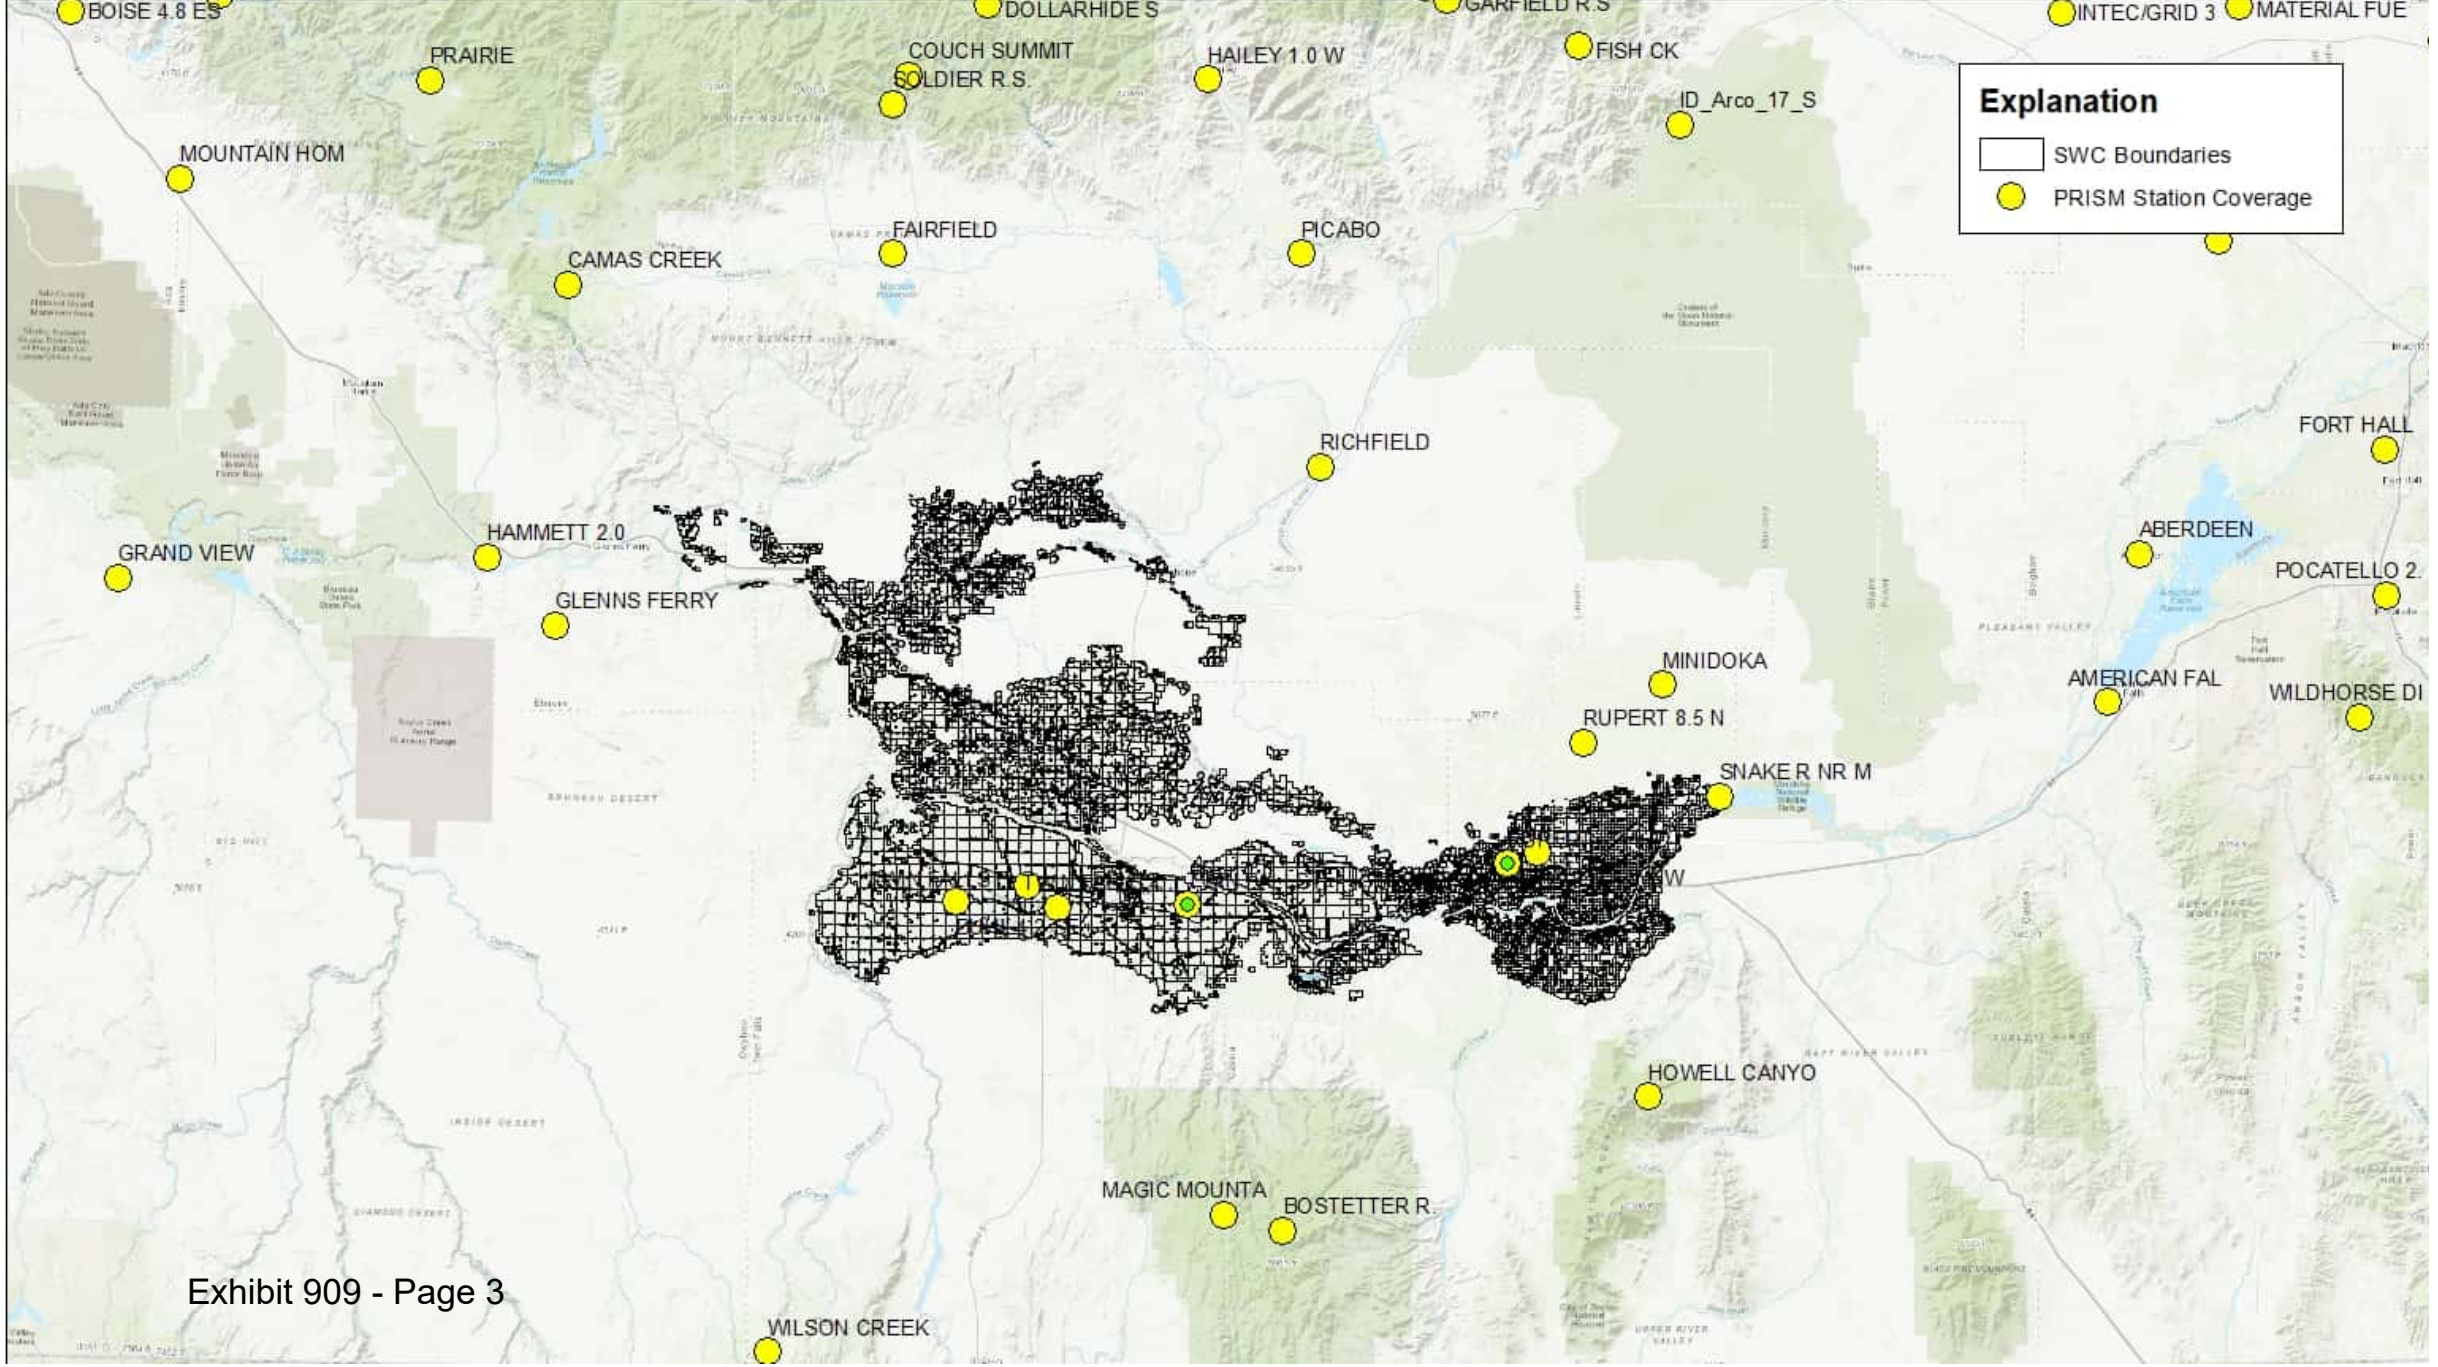
Proposed Modification to Method for Determining Reasonable In-Season Demand for the Surface Water Coalition: Use of the Near Real Time METRIC

Presented by Ethan Geisler

December 9, 2022

IDAHO DEPARTMENT OF WATER RESOURCES

PRISM Station Coverage and Final vs Provisional Difference Analysis for 2021



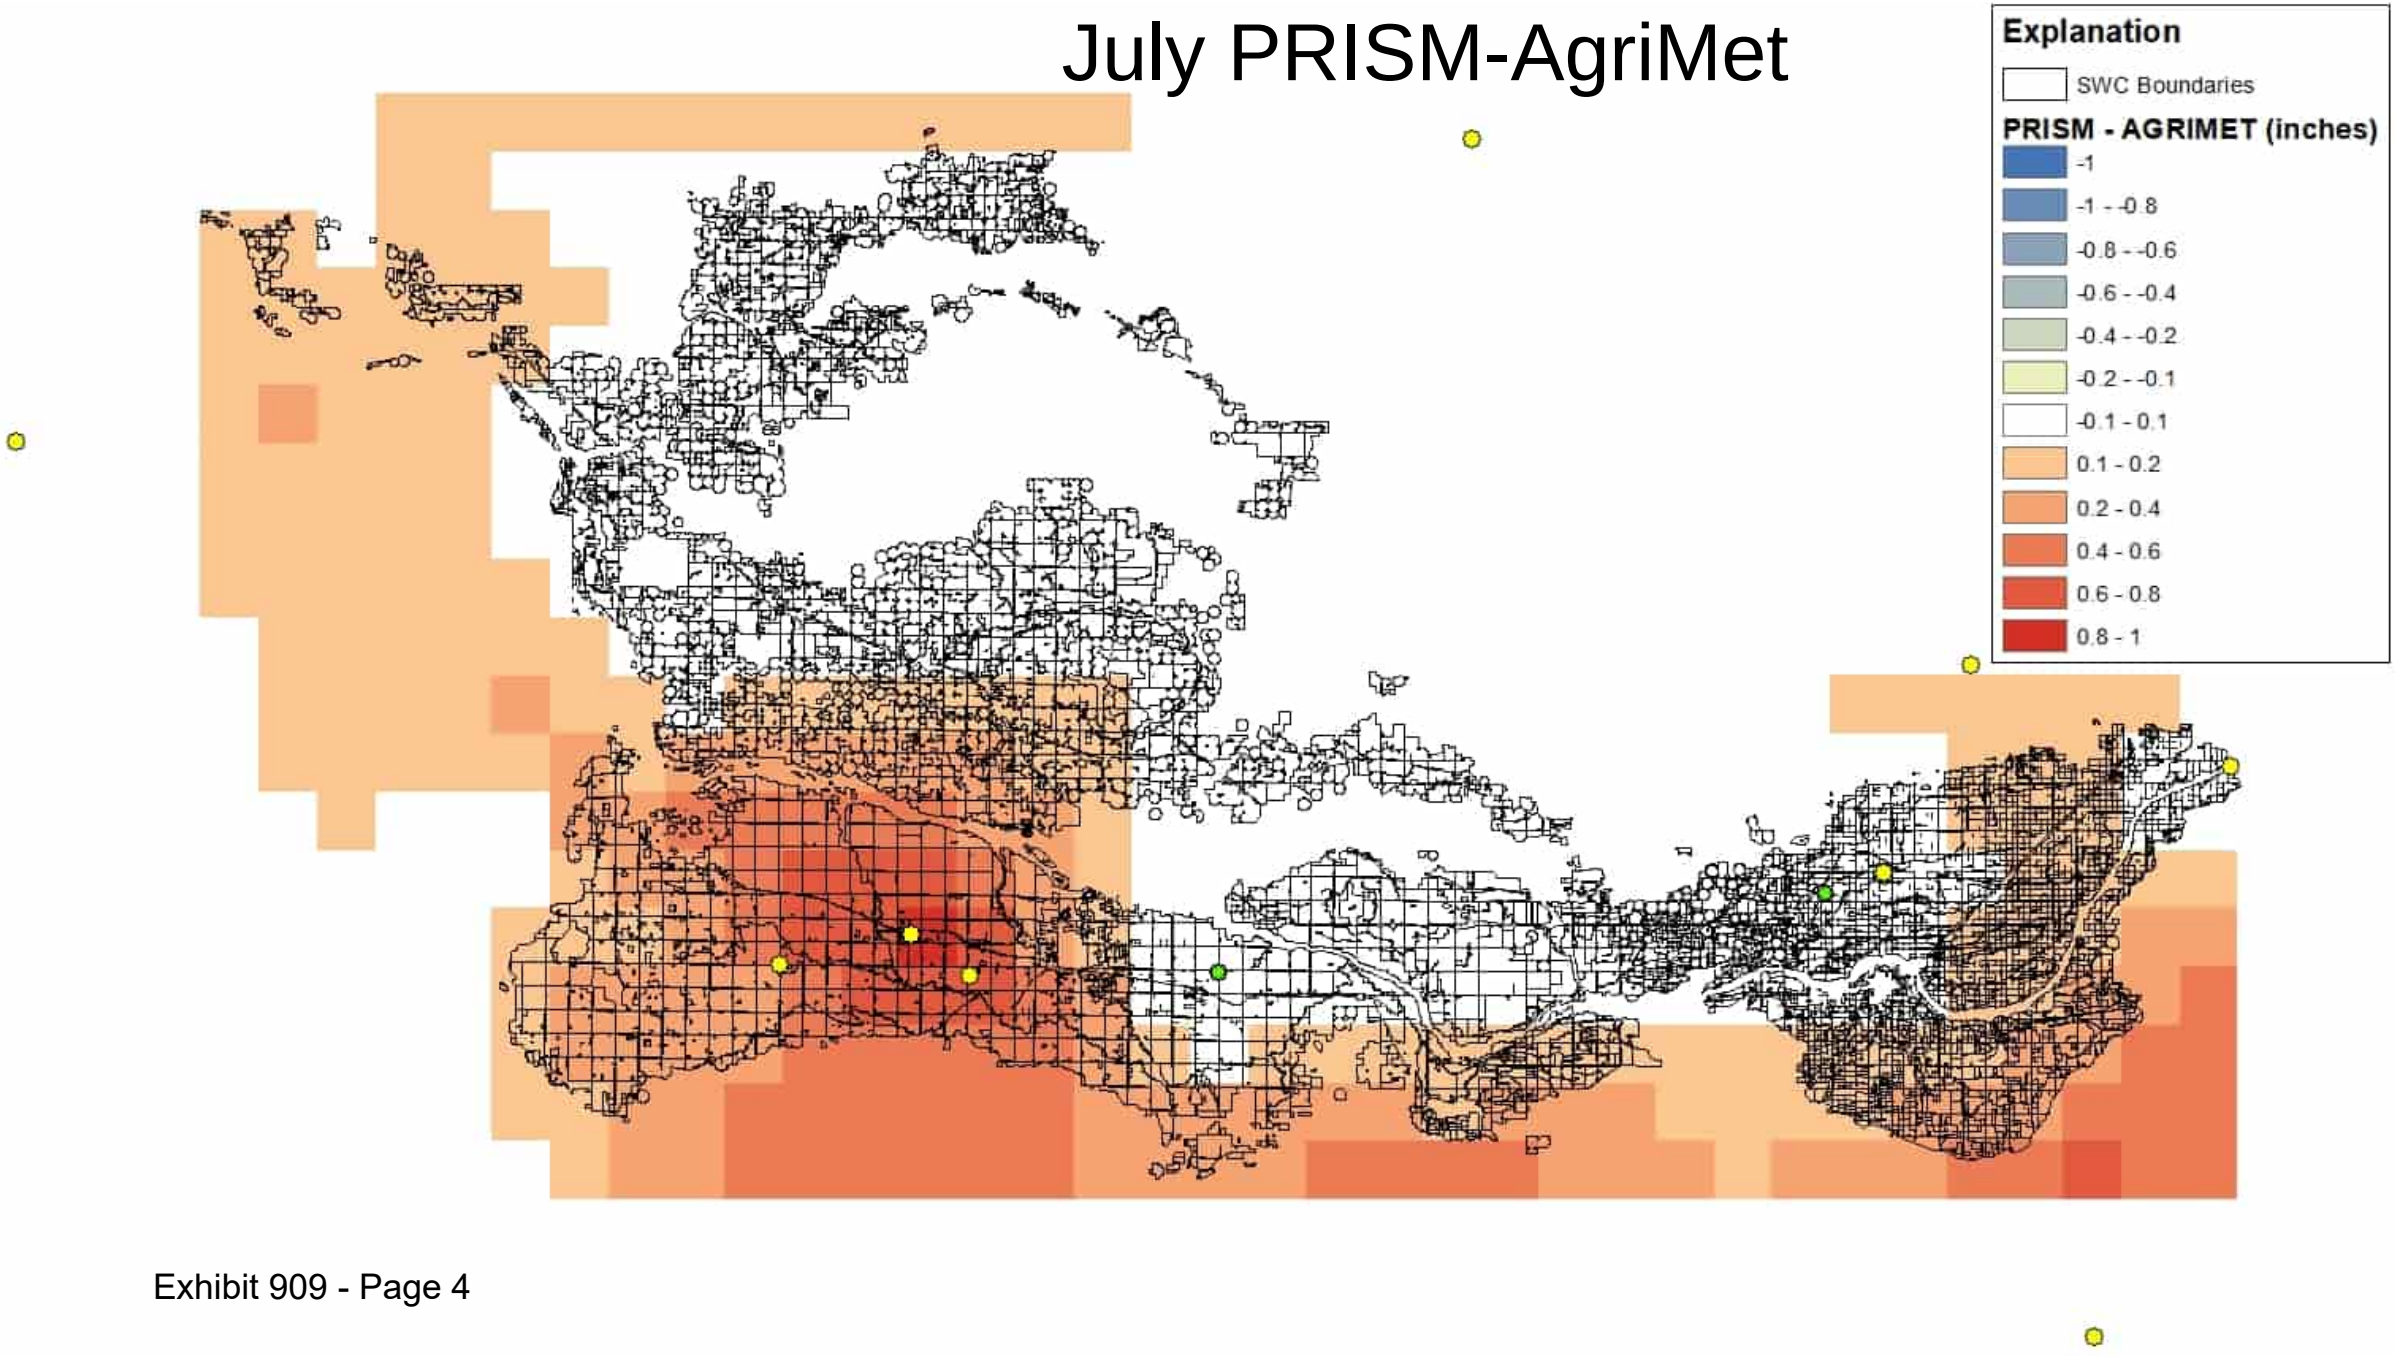


Exhibit 909 - Page 3

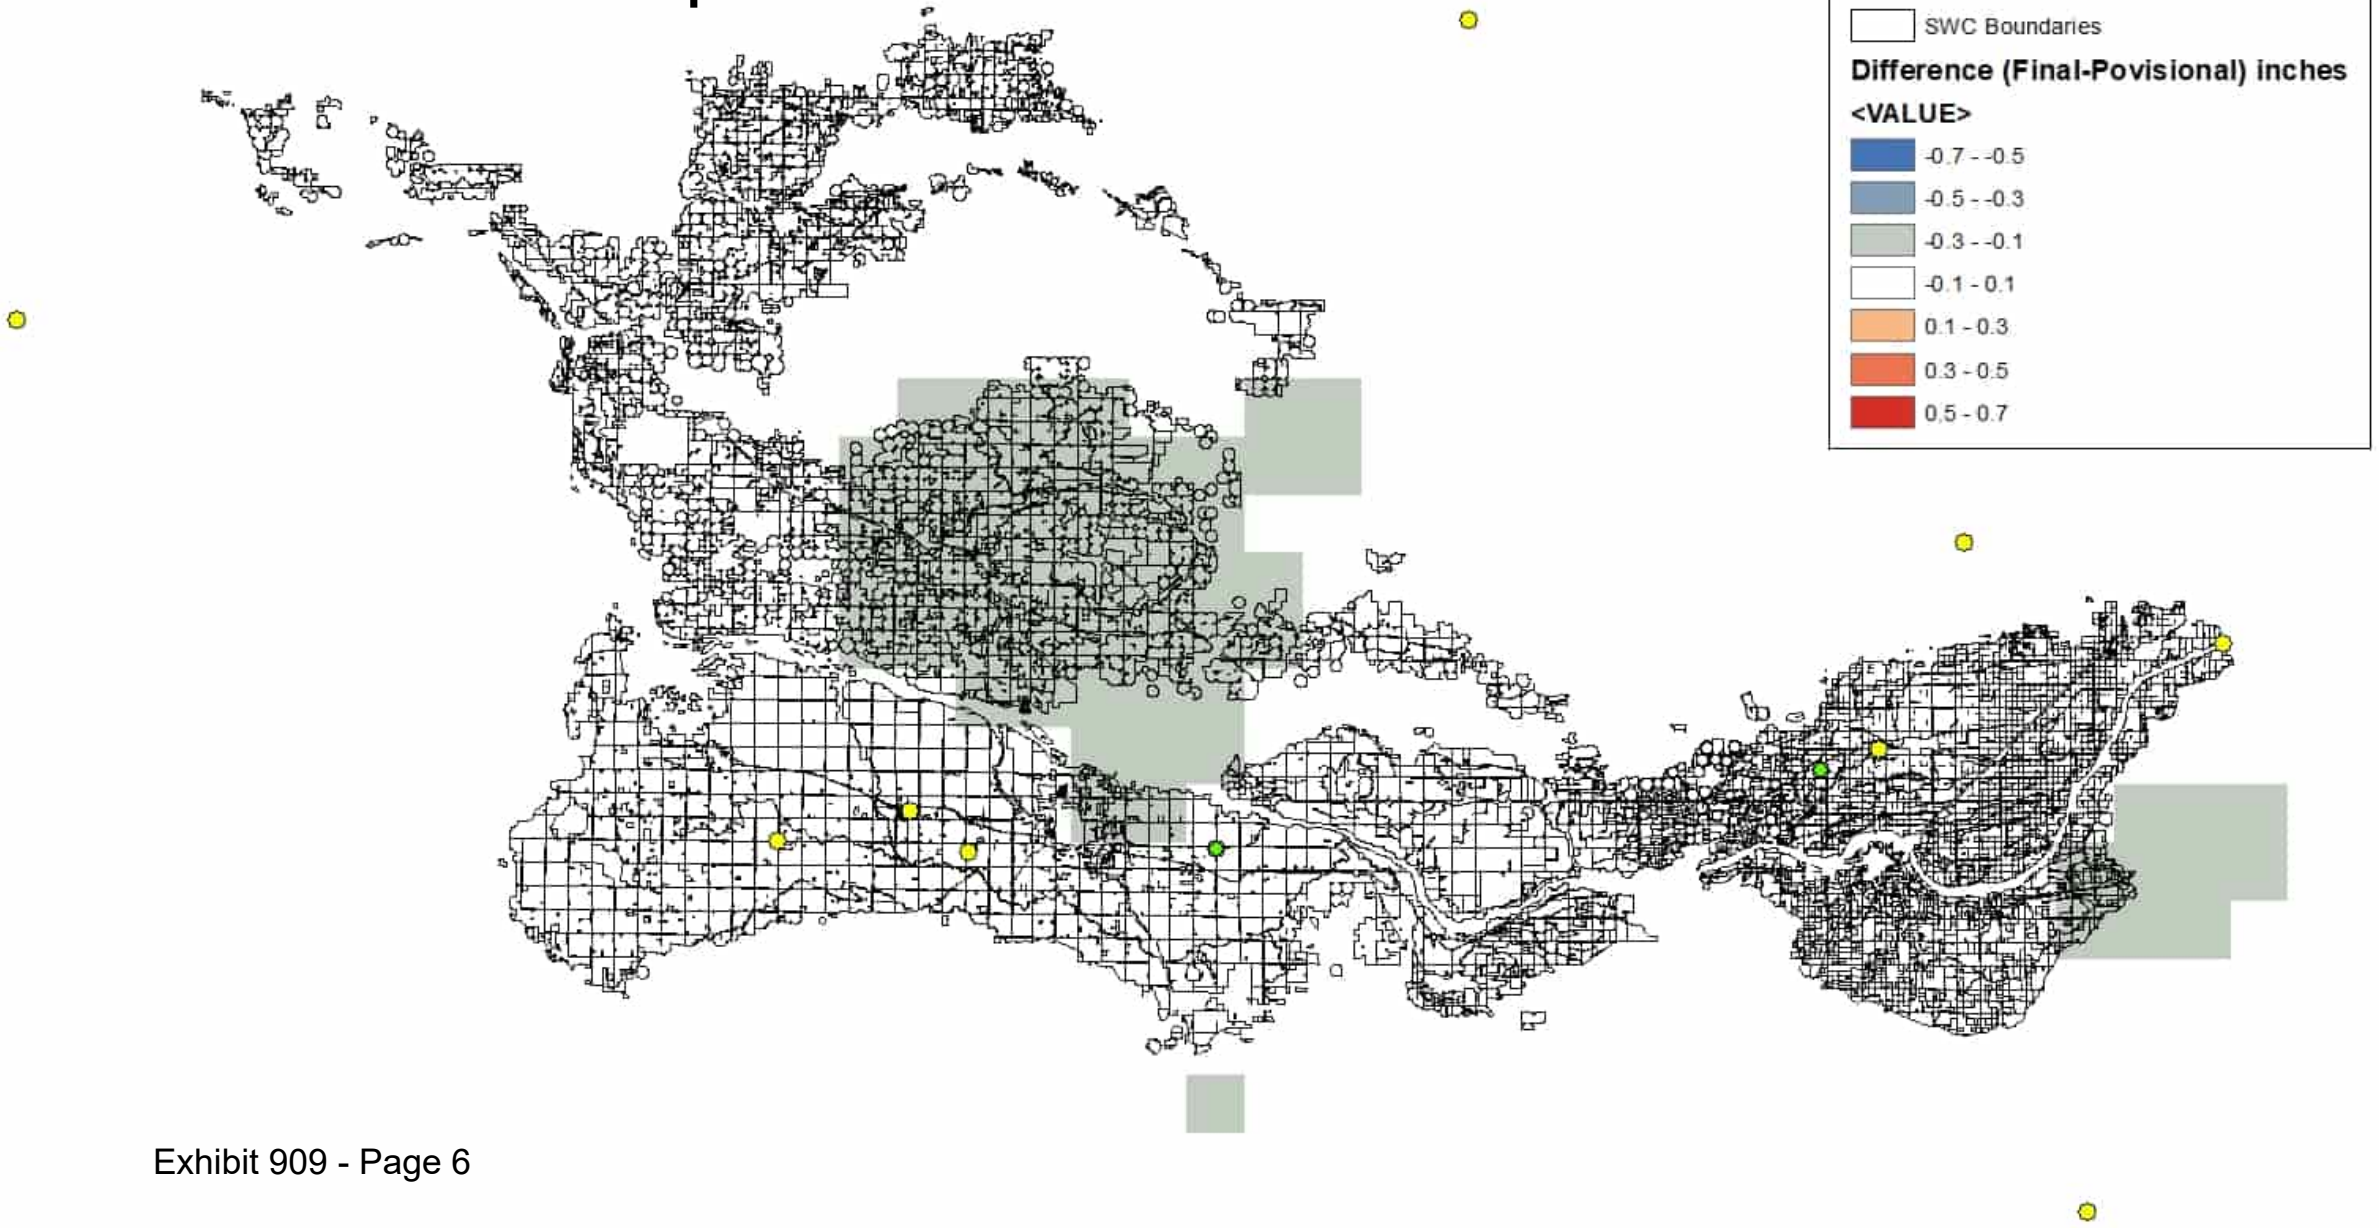
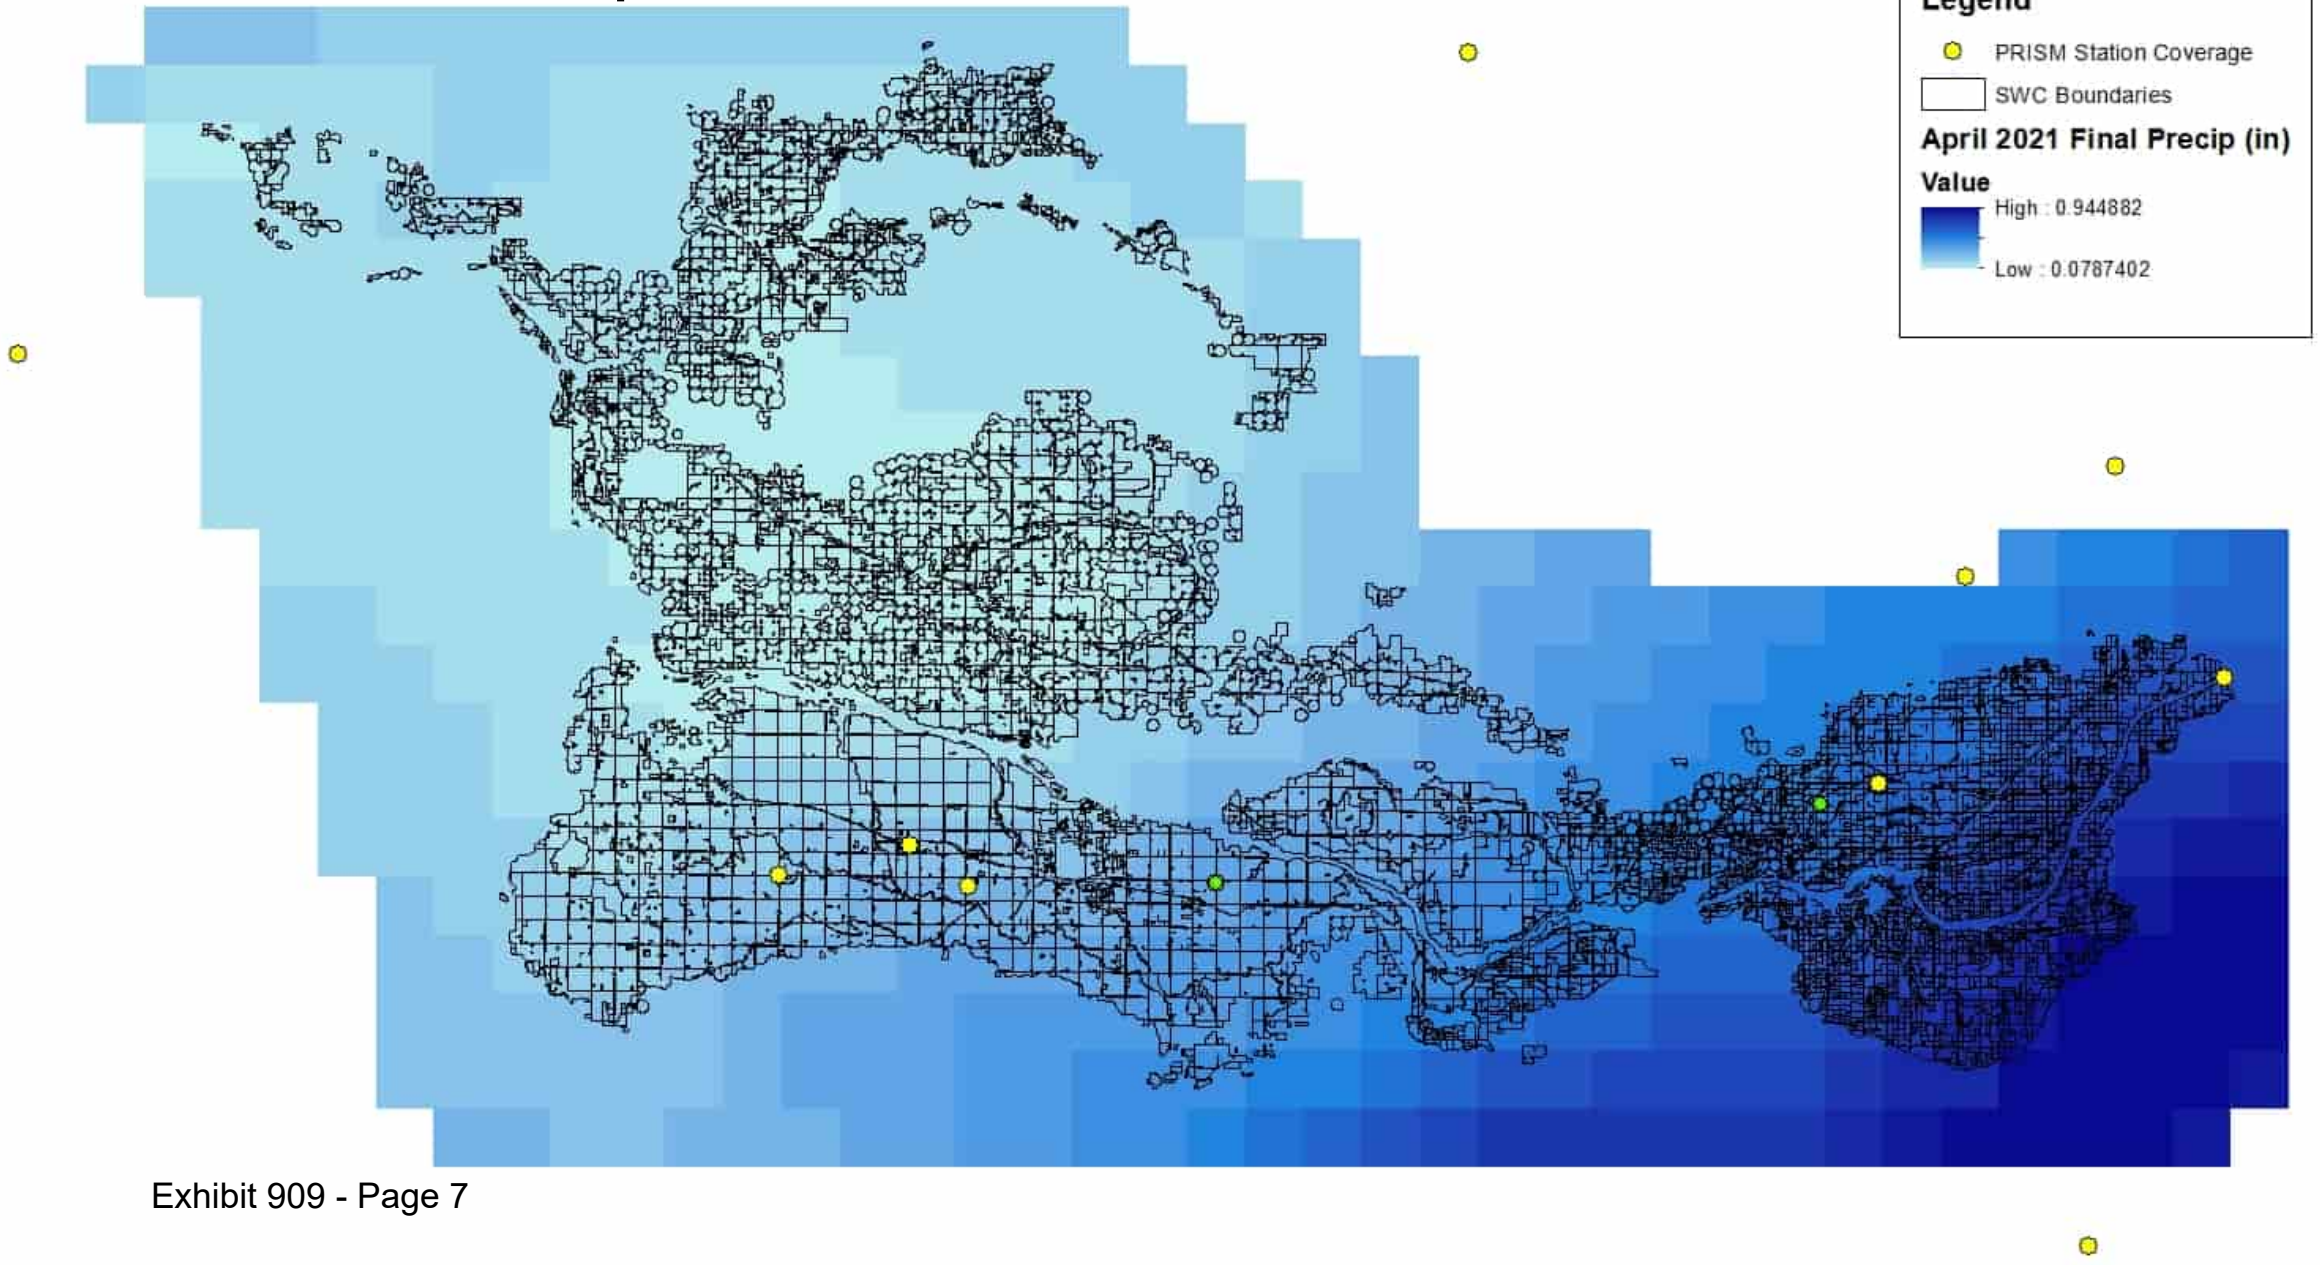
July PRISM-AgriMet

2021 PRISM Provisional data vs Final data



- Values (in inches) represent the difference between Final PRISM data and the real-time Provisional PRISM data.

- Negative value in the graphs below indicates Provisional PRISM was higher than Final PRISM
  - Crop Water Need would be underestimated with Provisional PRISM compared to Final PRISM



- Positive values in the graphs below indicated Final PRISM was higher than Provisional PRISM
  - Crop Water Need would be overestimated with Provisional PRISM compared to Final PRISM

- White background indicates the difference was between -0.1 and 0.1 inches, with very little change between provisional and final.

Proposed Modification of the Methodology For Determining Material Injury To Reasonable In-Season Demand and Reasonable Carryover: Reasonable Carryover

Presented by: Matt Anders

Date: 12/9/2022

Methodology Reference

- Reasonable Carryover (Page 21 of Methodology)
  - Conjunctive Management Rule 42.01.g states the following guidance for determining reasonable carryover: "In determining a reasonable amount of carry-over storage water, the Director shall consider average annual rate of fill of storage reservoirs and the average annual carry-over for prior comparable water conditions and the projected water supply for the system."
  - Carryover shortfall will be determined following the completion of the irrigation season.
  - Because it is not possible to adequately forecast the irrigation supply or demand for the following irrigation season at the end of the current irrigation season, the Director must estimate the carryover water needed in future dry years when demand exceeds supply, creating a need for carryover storage.
  - The Director projected the water supply using typical dry years and subtracted it from a projected future demand to determine a projected carryover need.

Methodology Reference

- Reasonable Carryover (Page 23 of Methodology)
  - Projected Carryover Need = Projected Demand (06/08/12 BLY) - Projected Supply (Average 02/04)

	Projected Demand (06/08/12 BLY)	Projected Supply (Average 02/04)	Projected Carryover Need
	----------Acre-Feet----------

02/04 as Predictor of Total Water Supply?

- For the years 2002 and 2004 the Heise natural flows were well below the long-term average (1991-2014) but were not the lowest years on record.

- The average of the 2002 and 2004 supply will be the projected supply, representing a typical dry year.

Summary of Recommended Technical Revisions to the 4th Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover for the Surface Water Coalition

12/23/2022

By: Kara Ferguson, Staff Hydrologist & Matt Anders, Hydrology Section Supervisor

In a status conference on August 5, 2022, the Director of the Idaho Department of Water Resources (IDWR) issued a directive to IDWR staff to convene a committee of experts to review and provide comments on potential technical changes to the "Fourth Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover" (Methodology) issued on April 19, 2016. IDWR staff created a technical working group composed of IDWR staff, experts representing the parties to the ongoing Surface Water Coalition (SWC) delivery call, and other interested parties. IDWR identified potential technical changes to the Methodology and presented them to the technical working group for discussion.

IDWR hosted six technical working group meetings between November 16 and December 14, 2022. Before each meeting, IDWR staff circulated PowerPoint presentations and agendas to the working group. The meetings were attended by interested members of the public and consultants and attorneys for parties to the SWC delivery call. Department staff and attorneys also participated. The meetings included presentations by IDWR staff and working group members, as well as open discussion on the topics presented. During the final meeting on December 14, 2022, IDWR staff stated that IDWR would provide a document summarizing staff's preliminary recommendations on potential technical changes to the Methodology.

Based on the information presented at the meetings and distributed to the technical working group, IDWR staff have the following preliminary technical recommendations:

- Update the Baseline Year (BLY) irrigation demand used to determine reasonable in-season demand from the current average of diversion demands for the 2006, 2008, and 2012 irrigation seasons to the diversion demand for the 2018 irrigation season.
- Update the BLY irrigation demand used to determine reasonable carryover for each SWC member from the current average of the diversion demands for the 2006, 2008, and 2012 irrigation seasons to the diversion demand for the 2018 irrigation season.
- Update the project efficiency value used to calculate monthly reasonable in-season demand from a rolling average of the previous eight years to a rolling average of the previous fifteen years.

At this time, staff do not have recommendations on utilizing near real time METRIC for determining crop water need, updating April and July regressions to improve their predictive power for natural flow supply, or using transient model simulation for determining curtailment priority dates. IDWR will continue to evaluate the integration of these and other techniques into the methodology.

IDWR requests written comments from the technical working group on the above recommendations or any other topic covered during the meetings. Please submit any comments no later than January 16, 2023, to matthew.anders@idwr.idaho.gov.

DATE: January 16, 2023

RE: Comments on behalf of the Coalition of Cities and the City of Pocatello on the Idaho Department of Resources Summary of Recommended Technical Revisions to the 4th Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover for the Surface Water Coalition, by Kara Ferguson and Matt Anders on December 23, 2022.

Under direction of the Director of the Idaho Department of Water Resources ("IDWR"), IDWR staff organized a technical working group ("TWG") to provide comments on potential technical changes to the Fourth Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover ("SWC Methodology"). The SWC Methodology was first ordered on April 7, 2010 and last amended on April 19, 2016. IDWR held numerous TWG meetings between November 16 – December 14, 2022 and Greg Sullivan and Heidi Netter of Spronk Water Engineers, Inc. ("SWE") participated in all of them, along with representatives of the Coalition of Cities and the City of Pocatello ("Cities").

On December 12 and 21, 2022, during the period of the TWG meetings, SWE submitted comments to the TWG via emails with attachments (*see* **Attachments 1** and **2**). These comments are made on behalf of the Cities to elaborate on the comments and materials previously provided.

IDWR Recommendations:

Following the conclusion of the TWG meetings, IDWR staff submitted a summary of three proposed changes to the SWC Methodology on December 23, 2022 that it recommends be implemented ("IDWR Recommendations"). The proposed changes consist of the following:

1. Update the Baseline Year ("BLY") irrigation demand used to determine reasonable in-season demand from the current average of diversion demands for the 2006, 2008, and 2012 irrigation seasons to the diversion demand for the 2018 irrigation season.

2. Update the BLY irrigation demand used to determine reasonable carryover for each SWC member from the current average of the diversion demands for the 2006, 2008, and 2012 irrigation seasons to the diversion demand for the 2018 irrigation season.

3. Update the project efficiency value used to calculate monthly reasonable in-season demand from a rolling average of the previous eight years to a rolling average of the previous fifteen years.

Comments on IDWR Recommendations:

Updated Baseline Year

IWDR staff recommends that the BLY be changed to 2018 because the previous BLY that is based on an average of conditions during 2006, 2008, and 2012 ("06/08/12") no longer reflects conditions during year(s) with above average diversions. During the meeting on November 16, 2022, IDWR presented information showing that combined SWC member diversions during 06/08/12 that averaged a combined 3,194,722 acre-feet and were 99.8% of the 2001 – 2021 average. This information showed that the SWC member diversions were no longer above average, but instead were very slightly below average. The combined SWC diversions during the proposed new BLY of 2018 are 186,000 acre-feet greater than the combined average diversions the 06/08/12 BLY. The increased diversions for the proposed new BLY will translate into greater projected shortages to the SWC members under the SWC Methodology.

A review of the data suggests that the 06/08/12 average diversions are no longer above average because the diversions by several of the SWC members have increased since the SWC Methodology was last updated in 2016. IWDR did not provide any information or analysis to explain why the SWC diversions have increased.

The information previously submitted by SWE on December 12 and 21, 2002 indicates that the computed Project Efficiency ("PE") for most of the SWC members has decreased or remained flat since the methodology was last updated in 2016. This is surprising given the continued sprinkler conversions and general advances in irrigation practices and technology that have occurred in the irrigation industry over the past 20 years. Only Minidoka shows a trend of significantly increasing efficiency. In addition, the low PE values for most SWC members during September and October are concerning.

The 2010 Fourth Amended Methodology Order states that "[d]uring periods of drought when groundwater users are subject to curtailment, members of the SWC should exercise reasonable efficiencies to promote the optimum utilization of the State's water resources." (paragraph 15). Application of the current SWC Methodology results in an unreasonable positive feedback loop for determination of the BLY: the more the SWC members divert, the greater the BLY diversions must be in order to stay above average. IDWR (or the TWG) should conduct additional analysis to determine whether the additional diversions are needed to meet crop demands, an analysis that could take the form of a basin-wide crop survey or other type of analysis. In the meantime, it is unreasonable to change the BLY in the manner that will increase shortages to the SWC members and result in greater curtailment of juniors.

Updated Project Efficiencies

IDWR proposes to change computation of the monthly average PE values from the average for the most recent 8 years to the average of the most recent 15 years. IDWR did not explain why it is proposing this

change. Changing from an 8-year average to a 15-year average may lessen the effect of recent reductions in PE for certain SWC members. The 2010 Order entails a "reasonable test" be applied to SWC member efficiencies. Here no reasonableness test has been applied, and as discussed in detail in **Attachment 1**, flat or decreasing PE values for the SWC members are concerning given continued sprinkler conversions by the SWC members and the advances in irrigation practices that continue to occur in the industry.

Other Comments

1. Irrigated acres provided by SWC should be accompanied by shapefiles to show that the reported irrigated acres reasonably match the actual irrigated lands. This can be confirmed using aerial imagery, field verification, and/or remote sensing such as NDVI, METRIC ET, and CDL.
2. The SWC Methodology provides that the crop water needs of the SWC members may be adjusted for supplemental groundwater use on the irrigated lands. IDWR should require that information necessary for this adjustment be compiled and utilized to adjust the reasonable in-season demand of the SWC members.

Attachments: 2022-12-12 SWC Diversions and CWN.xlsx

Attached is a spreadsheet containing the graphs and tables of historical adjusted diversions and crop water needs for the SWC members that I presented to the SWC TWG on Friday, December 9. The underlying IDWR data on which the graphs and tables are based are also included.

As discussed during the meeting, the graphs and tables in the spreadsheet suggest that use of crop water need and project efficiency as a predictor of demand in the SWC Methodology should be revisited.

Let me know if you have any questions.

Thanks,

Greg

Subject: Updated Comparison of Adjusted Diversions and Crop Water Needs for SWC Members
Attachments: 2022-12-21 SWC Diversions and CWN.xlsx; 2022-12-21 SWC Diversions and CWN Charts.pdf

TWG Members:

Attached is updated version of the spreadsheet comparing the historical Adjusted Diversions and Crop Water Needs (CWN) for the SWC members during 2001 – 2021. The spreadsheet includes several additional charts described below. PDFs of the added charts are attached.

Annual Project Efficiency Time-Series (AnnChartsPE Tab)

Additional charts were added in columns S – AH showing the computed annual Project Efficiency (PE) for each SWC member during from 2001 – 2021. The input flags that can be used to exclude certain years from the analysis (set on the AB tab) also operate to limit the annual efficiency values that are plotted in the new graphs. The flag in the attached spreadsheet is currently set to exclude years with a Demand Shortfall (DS) [flag = 2]. The trendlines plotted on the graphs indicate generally flat or declining PE for 6 of the 7 SWC members. This is surprising given the continued sprinkler conversions and general advances in irrigation practices and technology that have occurred in the irrigation industry over the past 20 years. Only Minidoka shows a trend of significantly increasing efficiency. The following are the changes in PE from 2001 – 2021 indicated by the trendlines for each SWC member:

Change in Project Efficiency (2001-2021)
(percentage point change)

A&B	-4.6%
AFRD2	-3.6%
BID	-1.0%
Milner	-12.6%
Minidoka	+12.2%
NSCC	-3.0%
TFCC	+1.8%

Because the PE values used in the SWC Methodology are currently based on averages for the most recent 8 years, any declines in the computed PE values will translate into increased demands and increased shortages.

Annual Project Efficiency vs Annual Adjusted Diversions AND Annual Crop Water Need (AnnAll Tab)

Additional scatter diagrams were added in columns AG – BM to plot the Annual Project Efficiency (PE) vs the Annual Adjusted Diversions AND Annual Crop Water Need for the 2001 – 2021 period. Again, the flag in the attached spreadsheet is set to exclude years with computed Demand Shortfalls (DS). Also plotted on the Annual Adjusted Diversions scatter charts are the average PE (solid black line) and the average PE + 1 standard deviation (dotted black line).

Monthly vs. Annual Project Efficiencies (AnnAll Tab)

Charts were added in columns BO – CD that compare the monthly average PE, average annual PE, and average annual PE + 1 standard deviation for each SWC member. These charts illustrate the low PE values in some months that cause monthly demands computed based on CWN / PE to be very sensitive to changes in CWN.

Discussion

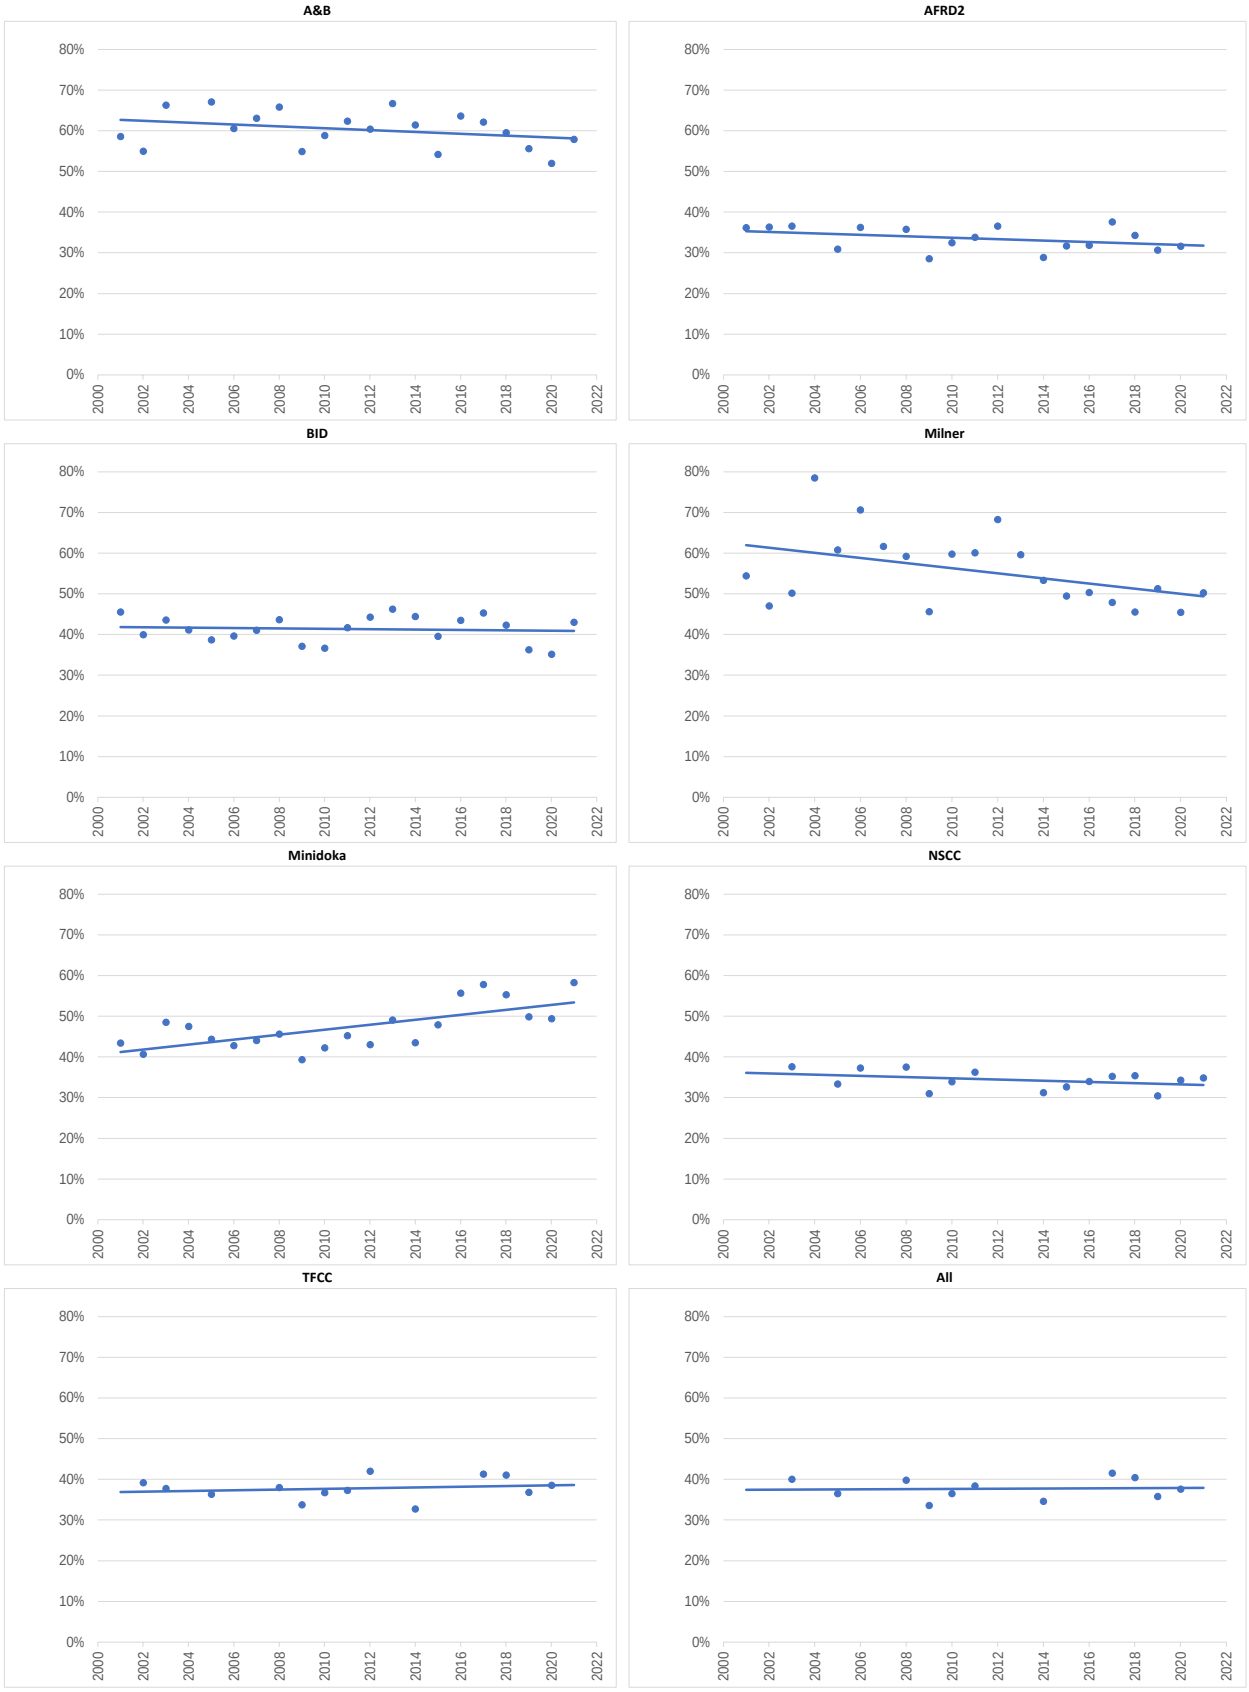
The current SWC Methodology uses Monthly CWN / Avg Monthly PE to compute the monthly Diversion Demand. The Avg Monthly PE values for many of the SWC members vary widely throughout the irrigation season, and are unreasonably low in some months, particularly in September and October. The low monthly PE values may be due in part because they do not reflect the portion of the diversions that may be stored in soil moisture for subsequent use. For example, consider a month with 100 AF diverted, 30 AF of CWN, and 20 AF accruing to soil moisture. Under the SWC methodology, the computed PE would be 30%, but the actual PE considering the water stored in soil moisture would be 50%.

Because of the wide variability in the computed monthly PE values, consideration should be given to using seasonal PE values rather than monthly PE values in computing the monthly Diversion Demands. This would help level out the wide swings in the monthly diversion demands that sometimes occur in application of the SWC Methodology when relatively low monthly PE values are divided into relatively high monthly CWN values. If seasonal PE values are utilized, the data for September and October should be reviewed and potentially excluded from calculation of the seasonal PE values since the efficiencies in those months are unreasonably low.

In addition, the current use of average PE values during the most recent 8 years in the Diversion Demand calculations should be reviewed. The 2010 Fourth Amended Methodology Order states that "[d]uring periods of drought when junior groundwater users are subject to curtailment, members of the SWC should exercise reasonable efficiencies to promote the optimum utilization of the State's water resources." (paragraph 15). The annual PE values shown in the above referenced graphs show significant year-to-year variations for each SWC member. Since the data in the charts have been filtered to exclude years with computed demand shortages, variations in the computed annual PE values indicate that each of the SWC members have operated at a range of efficiencies to meet crop water demands over the past 20 years. Given the level or declining trend in average efficiencies for most SWC members, the current methodology that uses average efficiencies for the most recent 8 years may discourage reasonable and efficient use by the SWC to the detriment of groundwater users and contrary to optimum utilization of the State's water resources.

The following table compares the average annual PE values for 2014-2021 (most recent 8-year period) against alternate PE values computed from annual data and April – August data for 2001-2021. The alternate PE values are tabulated as averages and as averages plus 1 standard deviation. All values exclude years in which demand shortages were computed.

PE Summaries	A&B	AFRD2	BID	Milner	Minidoka	NSCC	TFCC
2014-2021 Avg	58%	32%	41%	49%	52%	34%	38%
2001-2021 Avg	60%	34%	41%	56%	47%	34%	38%
2001-2021 Avg + 1 Std Dev	65%	36%	45%	65%	53%	37%	41%
2001-2021 (Apr-Aug) Avg	63%	36%	44%	58%	50%	37%	43%
2001-2021 (Apr-Aug) Avg + 1 Std Dev	68%	39%	48%	68%	55%	40%	46%



The above values are computed in columns CF – CU in the AnnAll tab in the attached spreadsheet. These values illustrate some different ways that annual and seasonal PE values can be computed from the historical data. If IDWR is going to continue computing Reasonable In Season Demand (RISD) based on CWN / PE, consideration should be given to using PE values that better reflect reasonable and efficient operations of the SWC members than do the historical averages that are currently used in the SWC Methodology. This would help ensure that curtailment and/or mitigation of impacts from junior groundwater use occurs when SWC supplies are short under reasonable and efficient operations.

Thanks,

Greg

MEMORANDUM

To: Matt Anders and Kara Ferguson, IDWR

From: Sophia C. Sigstedt, Lynker

Subject: Comments on 2022 IDWR Staff Recommendations

Date: January 16, 2023

This memorandum addresses my comments on the analyses presented to the 2022 Technical Working Group (TWG) related to revisions to the Methodology Order for determining injury to water rights held by members of the Surface Water Coalition. It serves as an addendum to Idaho Department of Water Resources (IDWR or Department) staff recommendations for the 2022 Methodology Update. IDWR staff and other members of the TWG presented analyses and recommendations regarding the following topics:

1. Baseline Year (BLY)
2. Forecasting Natural Flow Supply
3. Near-Real-Time METRIC for ET
4. Project Efficiency (PE)
5. ESPAM2.2 Steady State v. Transient

IDWR staff proposed changes related to BLY and PE, but only presented the results of internal analysis without recommending changes to the other topics investigated. TWG members were asked to consider whether the proposed recommendations provide a better technical basis than the current technique, or if there was an alternative with a better technical basis.

Sections 1-5 summarize my comments based on the proceedings for each TWG topic as listed above, respectively.

The topics identified above are not the only items in the Amended Methodology Order that should be considered regarding technical improvements. The comments in this memo are primarily in response to recommended changes made by IDWR staff in their memorandum dated December 23rd, 2022[1] and should not be considered a comprehensive summary of my opinions on all the technical aspects presented to the TWG or any other outstanding issues in the proceeding.

Section 1: Baseline Year Update

The IDWR staff recommended:

- Update the BLY irrigation demand used to determine Reasonable In-Season Demand (RISD) from the current average of diversion demands for the 2006, 2008, and 2012 (06/08/12) irrigation seasons to the diversion demand for the 2018 irrigation season.
- Update the BLY irrigation demand used to determine Reasonable Carryover for each SWC member from the current average of diversion demands for the 06/08/12 irrigation seasons to the diversion demand for the 2018 irrigation season.

[1] Summary of Recommended Technical Revisions to the 4th Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover for the Surface Water Coalition (IDWR, December 23rd 2022)

Lynker
5445 Conestoga Court, Suite 100
Boulder, Colorado 80301

In my opinion the recommendation to replace average diversions for the 06/08/12 irrigation seasons with single-year diversions in 2018 as the BLY does not have an adequate technical basis, and alternatives should be considered due to the following:

1. IDWR should consider rank within the period-of-record (POR) and select an average of years closer to the rank of the 06/08/12 BLY selected in 2015. IDWR staff presented analysis to the TWG for individual years 2018 and 2020 for consideration as the updated BLY. Either of these individual years are inadequate to represent reasonably dry baseline conditions for SWC diversions.

   When the average of diversion demands for the 06/08/12 irrigation seasons was selected as the BLY in 2015, the 06/08/12 average ranked between 7th and 8th highest for diversions, or about the 55th percentile (based on a normal distribution), for the POR 2000-2015 (**Figure 1**). IDWR staff presented analysis of Demand Shortfall calculations using 2018 and 2020 as an alternative BLY as they were both found to individually meet all the BLY criteria as shown in **Table 1**. For the POR 2000-2021 the diversion demand for 2018 and 2020 rank 3rd and 2nd, respectively, highest for diversions out of the 22 years, or about the 90th and 95th percentile (based on a normal distribution) for the POR (**Figure 2**).

   In a hindcast analysis by IDWR staff, the higher rank in BLY SWC diversions appears to cause a huge shift in the type of water year (i.e. wet, average, dry, very dry) where Demand Shortfalls are calculated. The hindcast showed a Demand Shortfall much more frequently in average and even wet years in addition to every dry or very dry year. When you compare the distribution of SWC total diversion demands for the POR 2000-2015 compared to 2000-2021 in **Figures 1** and **2**, however, it is apparent that they are very similar with mean diversions of 3.16 maf and 3.2 maf, respectively. The standard deviation is also very similar for the POR 2000-2015 compared to 2000-2021 at 178,089 af and 178,587 af, respectively. The selection of the BLY is meant to be conservative as defined by the BLY criteria. The shift to SWC diversions of a much higher rank (compared to the previous BLY) like 2018 or 2020 translates to a much higher level of conservatism and is not technically justified given the similarity between mean diversions and the standard deviation for the 2000-2021 POR versus the 2000-2015 POR.

   The Methodology Order states that the BLY can be a year or an average of years that meet the BLY criteria (**Table 1**). IDWR staff considered rank within the POR when they recommend keeping the 2002 and 2004 average Heise natural flows as the Supply in the Reasonable Carryover calculation from the 4th Amended Methodology Order for the 2022 update[2]. The average of diversion demands for the 2006 and 2018 (06/18) irrigation seasons meet all the BLY criteria as shown in **Table 1** and is closer to the 55th percentile based on a normal distribution for diversions 2000-2021 similar to the rank of the BLY 06/08/12 (**Figures 1** and **2**) as applied in the 4th Amended Methodology Order. The BLY of 06/18 has a better technical basis than the proposed update to 2018 as the BLY.

Table 1. Baseline Year and Baseline Year Criteria

BLY Criteria	BLY Avg 06/18	BLY 2018	BLY 2020	Avg 2000-2021
Abv Avg SWC Diversions	3.22 maf	3.38 maf	3.53 maf	3.20 maf
Abv Avg GDD	2575 units	2550 units	2600 units	2495 units
Abv ET	1265 mm/d	1275 mm/d	1280 mm/d	1245 mm/d
Blw Avg Precipitation	3.9 in	2.6 in	2.7 in	4.5 in
Abv Avg SWC Supply	8.52 maf	9.00 maf	8.10 maf	7.70 maf

[2] Proposed Modification of the Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover: Reasonable Carryover (IDWR, presentation slide no. 4, December 9th, 2022)

Lynker

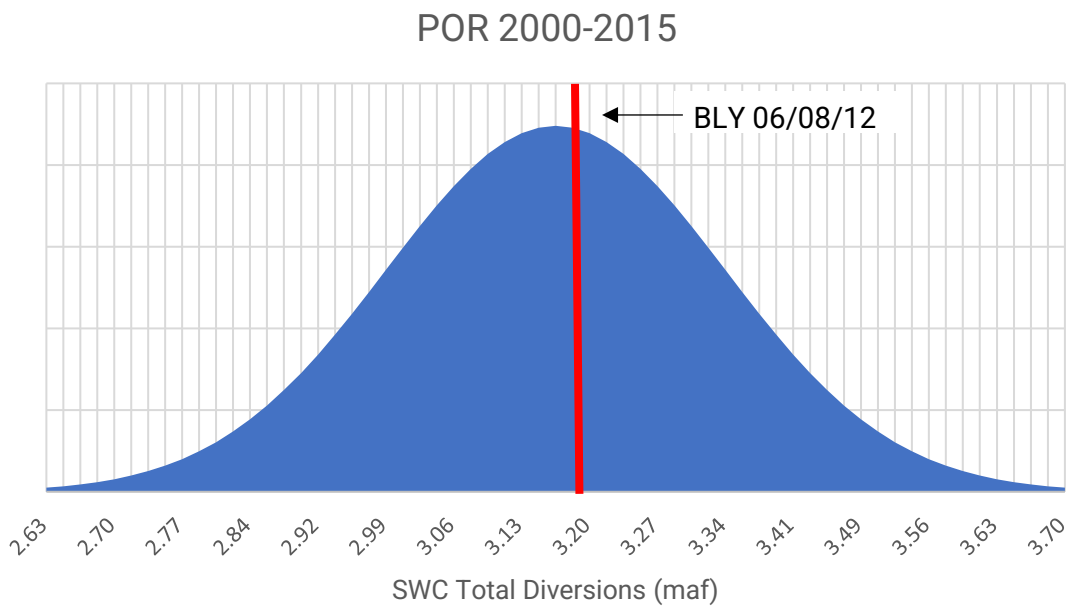

Figure 2. Normal distribution of SWC Total Diversion over the POR 2000-2015, the *red line* shows where the selected BLY 06/08/12 for the 4th Methodology Order falls within the normal distribution.

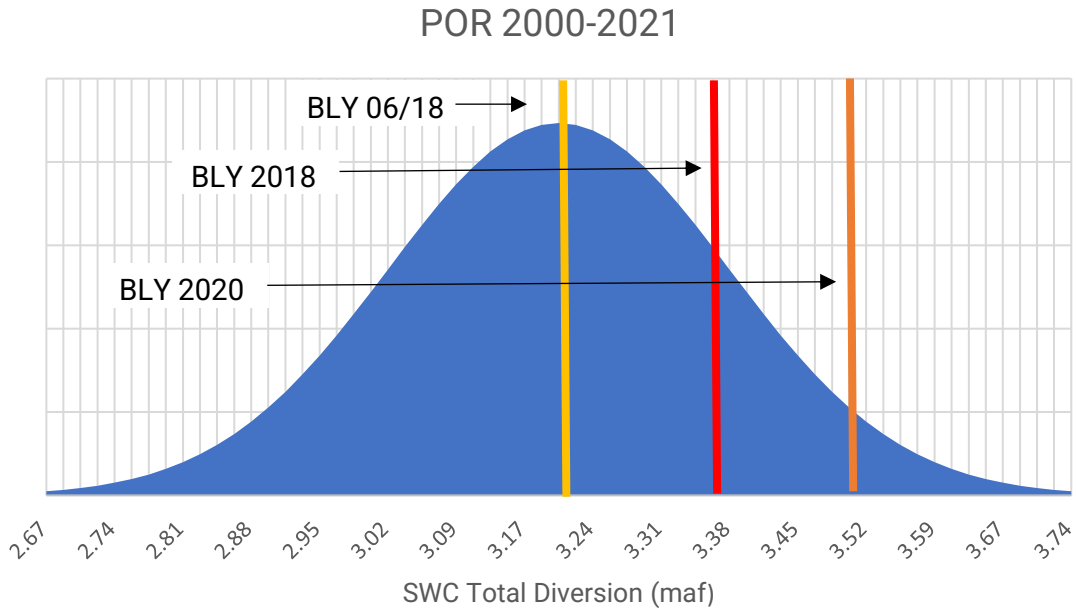

Figure 2. Normal distribution of SWC Total Diversion over the POR 2000-2021, the *yellow line*, *red line*, and *orange line* show where the proposed BLY 06/18, 2018 and 2020 falls within the normal distribution, respectively.

Lynker
5445 Conestoga Court, Suite 100
Boulder, Colorado 80301

2. Another reason a better alternative would be to use diversion demands for the 06/18 irrigation seasons for the BLY is that there were unique hydrologic circumstances in 2018 that I don't believe represent the typical dry year. The 2017/2018 snowpack was very high and water year forecasts and early season streamflow led to positive water supply forecasts which resulted in a record amount of aquifer recharge in 2018. IDWR staff acknowledged the technical difficulties in sorting out surface water adjustments like recharge in applying the Methodology Order. The combination of large volumes of widely distributed canal recharge, often in relatively rarely used or new systems, may have exacerbated uncertainty in the adjustment. The positive water supply outlook may have also resulted in less stringent surface water administration and ultimately higher diversions than the crop water need alone would predict. Consequently, using gross diversions in 2018 as the BLY effectively overstates surface water irrigation demand. IDWR staff presentations and a review of Twin Falls Agrimet station data also showed the 2018 irrigation season is the only year in the 1992-2021 POR with a zero-precipitation total for July-September. The fact that almost any individual water year will have some unique circumstance is a good reason for continuing to define the BLY based on an average of years as the Methodology Order does currently.
3. An additional reason for using a specific percentile (or rank) within the POR when establishing a BLY, and for using an average of years, is that the process for selection of the BLY otherwise appears arbitrary and subjective. If IDWR staff are presented with multiple years within the POR that fit the criteria for a BLY, and there is no guidance or standard method for selecting a single BLY, the ultimate selection becomes purely subjective. Using an average of years that targets a prescribed rank is a more objective and technically defensible process.

Section 2: Forecasting Natural Flow Supply

IDWR staff did not make a recommendation on updating April and July regression models to improve their predictive power for natural flow supply. The staff did make presentations to the TWG on natural flow forecasting models that showed the Twin Fall Canal Company (TFCC) model is degrading in the R^2 value. This degradation is significant in that the R^2 values is an expression of the explanatory power of the forecast model. The TFCC natural flow forecast models also started with the lowest R^2 values based on the previously revised forecast. The technical information presented to the TWG indicated that a revised natural flow method for TFCC should be evaluated and a recommendation for an improved method should be made. However, given the extremely compressed timeframe for staff and TWG members to conduct a thorough evaluation I understand why a recommendation was not made at this point.

Lynker's technical memorandum included as addendum to IDWR staff recommendations in 2015[3] laid out an alternative forecast model approach that I continue to think should be further investigated. The approach is creating a regression relationship or alternative model that forecasts the physical natural flow supply with subsequent allocation of that physical supply among the rights of the SWC. The technical basis for this suggestion is that water rights administration creates a non-continuous and non-normally distributed dependent variable in the regression analysis. This is likely the reason it is difficult to find a high performing regression model for TFCC.

The process for natural flow forecast model revision should also be standardized in-terms of defining how frequently a thorough re-evaluation of the predictors and models is done (i.e. 3-yrs, 5-yrs, if R^2 value drops below a threshold). This should include re-evaluating previously tested predictors over the new POR, as well as, casting a new net of total predictors for consideration by the TWG. While the TFCC model stands out in needing a refinement all of the models could be improved if sufficient time for the analysis were allowed. Several of the models utilize a depth to groundwater measurement as a predictor from a specific Sentinel Well flagged by a separate TWG (IGWA-SWC)[4], as likely impacted by American Falls Reservoir level.

Section 3: Near-Real-Time METRIC for ET

The IDWR staff did not make a recommendation on utilizing near-real-time METRIC for determining Crop Water Need (CWN) in the RISD calculation. The application of METRIC in the determination of crop demands deals with a complex dataset that requires complex processing. Given the magnitude of the task to incorporate METRIC data I understand the staff not making a recommendation at this time. The IDWR staff should keep track of the calculation utilizing the METRIC data in parallel to the current CWN calculation method as way to continue to evaluate its use. The Department's Eastern Snake Plain Aquifer (ESPA) model already utilizes METRIC data for consumptive use calculations used for model input data. Given the complexity of the METRIC data I also recommend further investigation into the method behind the calibration and processing of the dataset to determine how and to what extent the METRIC data can be validated at the field-scale or if there are common misrepresentations that should be considered in the process of data quality assurance checks. This should be done in coordination with validation efforts by the Department on their ESPAM Metric calibration and processing.

The IDWR staff presentation regarding near-real-time METRIC application identified a significant shortcoming in the current method for calculating CWN as the fact that the most up-to-date crop data is from the previous year and that SWC irrigated acre datasets sometimes represent service areas, not the actual irrigated land[5]. Non-irrigated acres should not be considered in determining the irrigation supply necessary for SWC members[6]. The METRIC data could first be used to create a standard review process for the Methodology Order Step 1 submittal of irrigated acres by the SWC entities. IDWR staff should use a precise determination of irrigated acreage irrespective of whether it uses METRIC in the calculation of CWN. With IDWR staff only checking against the total acres for the decreed place of use, there is little to no incentive to keep the spatial data for the irrigated acres up to date. The METRIC data would be available for the current irrigation season and can be used to assess actual irrigated land. Some of the preliminary analysis by IDWR staff using METRIC data illustrated that through processing they were able to identify about 15,000 acres within the TFCC irrigated acres dataset that should not qualify as irrigated. The mischaracterized acres were all minor areal corrections but over a large service area such as TFCC added up to a significant amount of erroneous total acres. This just highlights the importance of spending the time to get an accurate picture of irrigated acres for an accurate RISD calculation. As previously noted in Lynker's 2015 comment letter the 5% change standard for SWC submittals should be reconsidered in light of large districts like TFCC where a 5% error in the irrigated acres can result in calculation of tens of thousands of acre-feet of erroneous mitigation obligation. Liz Cresto an IDWR staff member on the TWG in 2015 also made a similar recommendation in her comment letter attached to the staff memorandum.

Neither the 2015 nor the 2022 TWG has provided an opportunity to address concerns regarding supplemental groundwater use. This is a critical aspect of the RISD calculation and was one of the specific technical items cited for revision by the District Court. Analysis of supplemental groundwater use is likely critical to accurately applying METRIC in the RISD calculation.

Section 4: Project Efficiency

The IDWR staff recommended:

- Update the project efficiency value used to calculate monthly reasonable in-season demand from a rolling average of the previous eight years to a rolling average of the previous fifteen years.

[5] Proposed Modification to Method for Determining Reasonable In-Season Demand for the Surface Water Coalition: Use of the Near Real Time Metric (IDWR, presentation slide no. 8, November 17th 2022)
[6] Second Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover-pg 4

Lynker
5445 Conestoga Court, Suite 100
Boulder, Colorado 80301

The technical basis for the IDWR staff recommendation was based on there being an extended POR available. TWG discussions and subsequent presentations identified other issues that should be considered in Methodology applications of project efficiency (PE) to RISD calculation.

1. There is higher uncertainty in the April and October project efficiency values. April and October represent months during the irrigation season when the method of calculating RISD strictly as a function CWN and PE is less reliable because CWN is often not the driving factor in diversions[7].
2. Project efficiency among SWC entities are almost all flat or declining (6 out of 7 entities), which is contrary to what would be expected with technology advancements and constrained water supplies[8].

Change in Project Efficiency (2001-2021) (percentage point change)	
A&B	-4.6%
AFRD2	-3.6%
BID	-1.0%
Milner	-12.6%
Minidoka	+12.2%
NSCC	-3.0%
TFCC	+1.8%

3. Scatter plots by SWC entity comparing Annual Crop Water Need to Annual Diversions show Crop Water Need is limited as a predictor given the low explanatory power indicated by the low R^2 values in the analysis[9].

Regarding the mid-season calculation of RISD, the sensitivity and appropriate use of CWN as a predictor for in-season demands for SWC entities should be evaluated. Technical analysis to the TWG showed that this is not a strong relationship[10]. This disconnect should be evaluated by the TWG so a recommendation can be made. The trends in declining PE are concerning in that they are contrary to our expectations given the direction technology advancements and constrained water supply. The declines in PE are significant in that any decline in PE will result in increased demands and subsequently increased calculated Demand Shortfalls. The IDWR staff presentation on PE illustrated how the very minor change in PE resulting from extending the POR for the average translated to tens of thousands of acre-feet differences in the Short Fall determination[11]. Sullivan (e-mail to TWG 12/21/2022) found that when analyzing monthly PE the low PE in some months cause monthly demands calculated based on CWN/PE to be very sensitive to changes in CWN. I agree with Sullivan's recommendation that given the outside influences and uncertainty in some of the monthly PE values IDWR staff should consider using a seasonal PE value in computing monthly diversion demands. I also agree with Sullivan's recommendation that consideration should be given to PE values that better reflect reasonable and efficient operations of SWC members. Given the observed declining trends in PE and the historically wide range in operational PE by entity it is hard to know when SWC supplies are short under reasonable and efficient operations. This is consistent with Lynker's 2015 recommendation for an investigation into trends among entities related to PE factors.

[7] Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover-pg 18
[8] Greg Sullivan e-mail, Updated Comparison of Adjusted Diversion and Crop Water Needs for SWC Members, to TWG December 21, 2022
[9] Analysis in Greg Sullivan datasheet "2022-12-21 SWC Diversions and CWN.xls"
[10] Analysis in Greg Sullivan datasheet "2022-12-21 SWC Diversions and CWN.xls"
[11] Proposed Modification of the Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover: Project Efficiency (IDWR, presentation slide no. 15, November 28th, 2022)

Lynker
5445 Conestoga Court, Suite 100
Boulder, Colorado 80301

Given the compressed timeframe around the 2022 TWG meeting there was not sufficient time for the TWG members to analyze or address these outstanding issues. Additional time should be set aside for the TWG to conduct an analysis and make a recommendation.

Section 5: Steady State v. Transient

The Department staff did not make a recommendation on using transient model simulation for determining curtailment priority dates in the Methodology. The IDWR staff presented to the TWG the following:

1. Technically the steady state application is not consistent with the variable curtailment dates and mitigation volumes under the Methodology.
2. Transient analysis shows that in-season shortfalls can generally not be met at Time of Need by in-season curtailment.
3. There is a huge difference in resulting determination of the curtailment priority date if a steady state v. transient model is applied.
4. Under a transient model application any Demand Shortfall above ~100K af would result in aquifer wide curtailment

It is not clear what additional analysis the Department staff need to conduct to make a recommendation on steady state v. transient model application. What is clear is that this represents a huge uncertainty to the water users and how they make planning and management decisions moving forward.

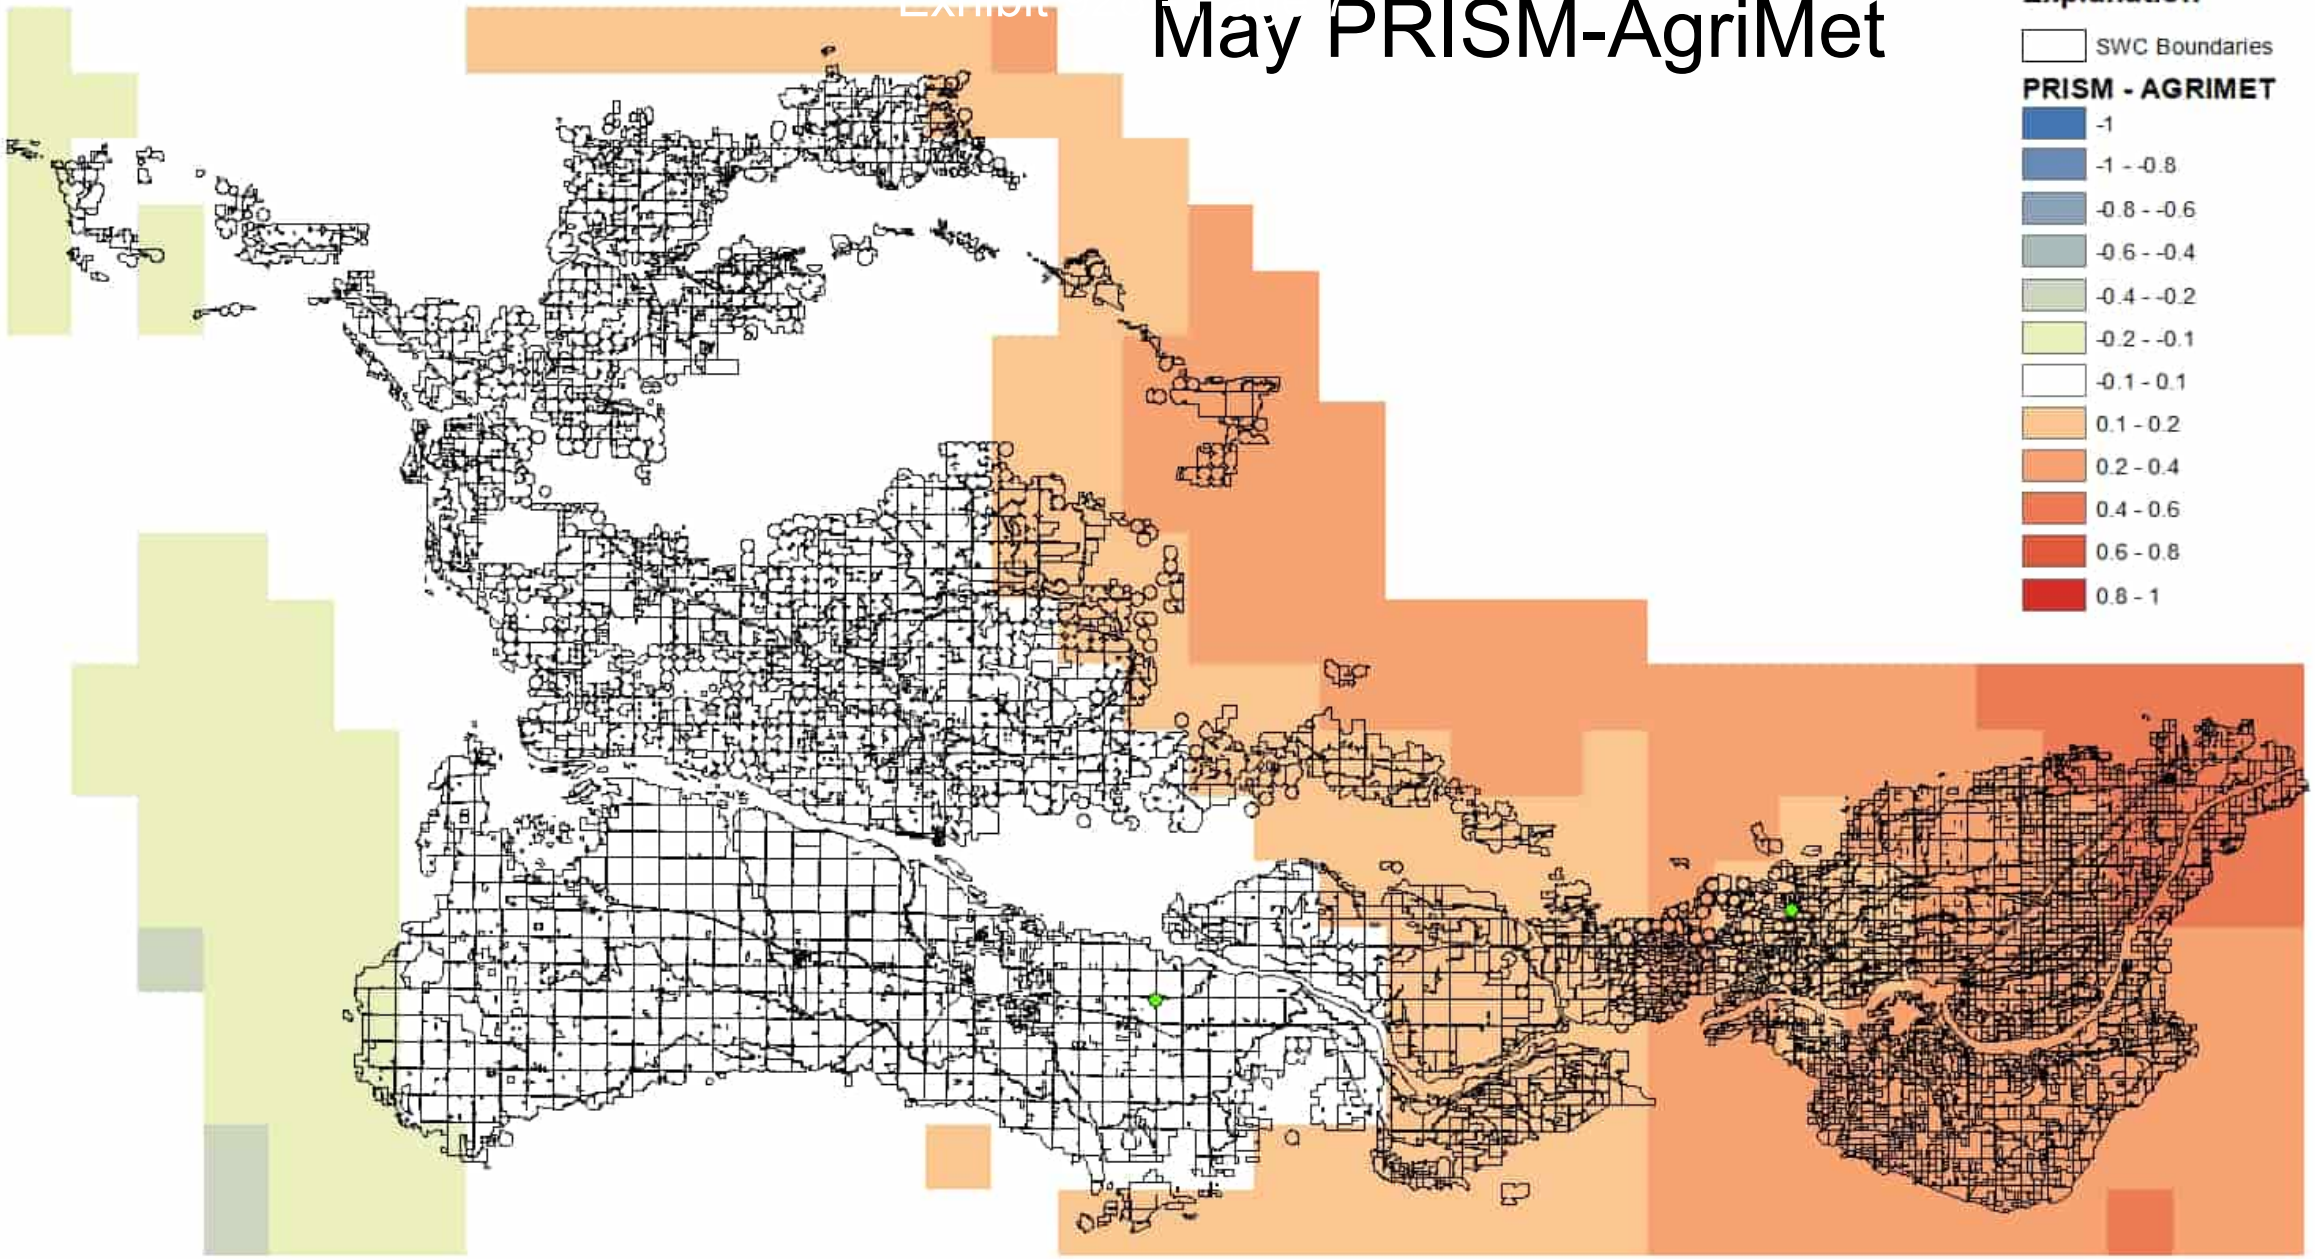
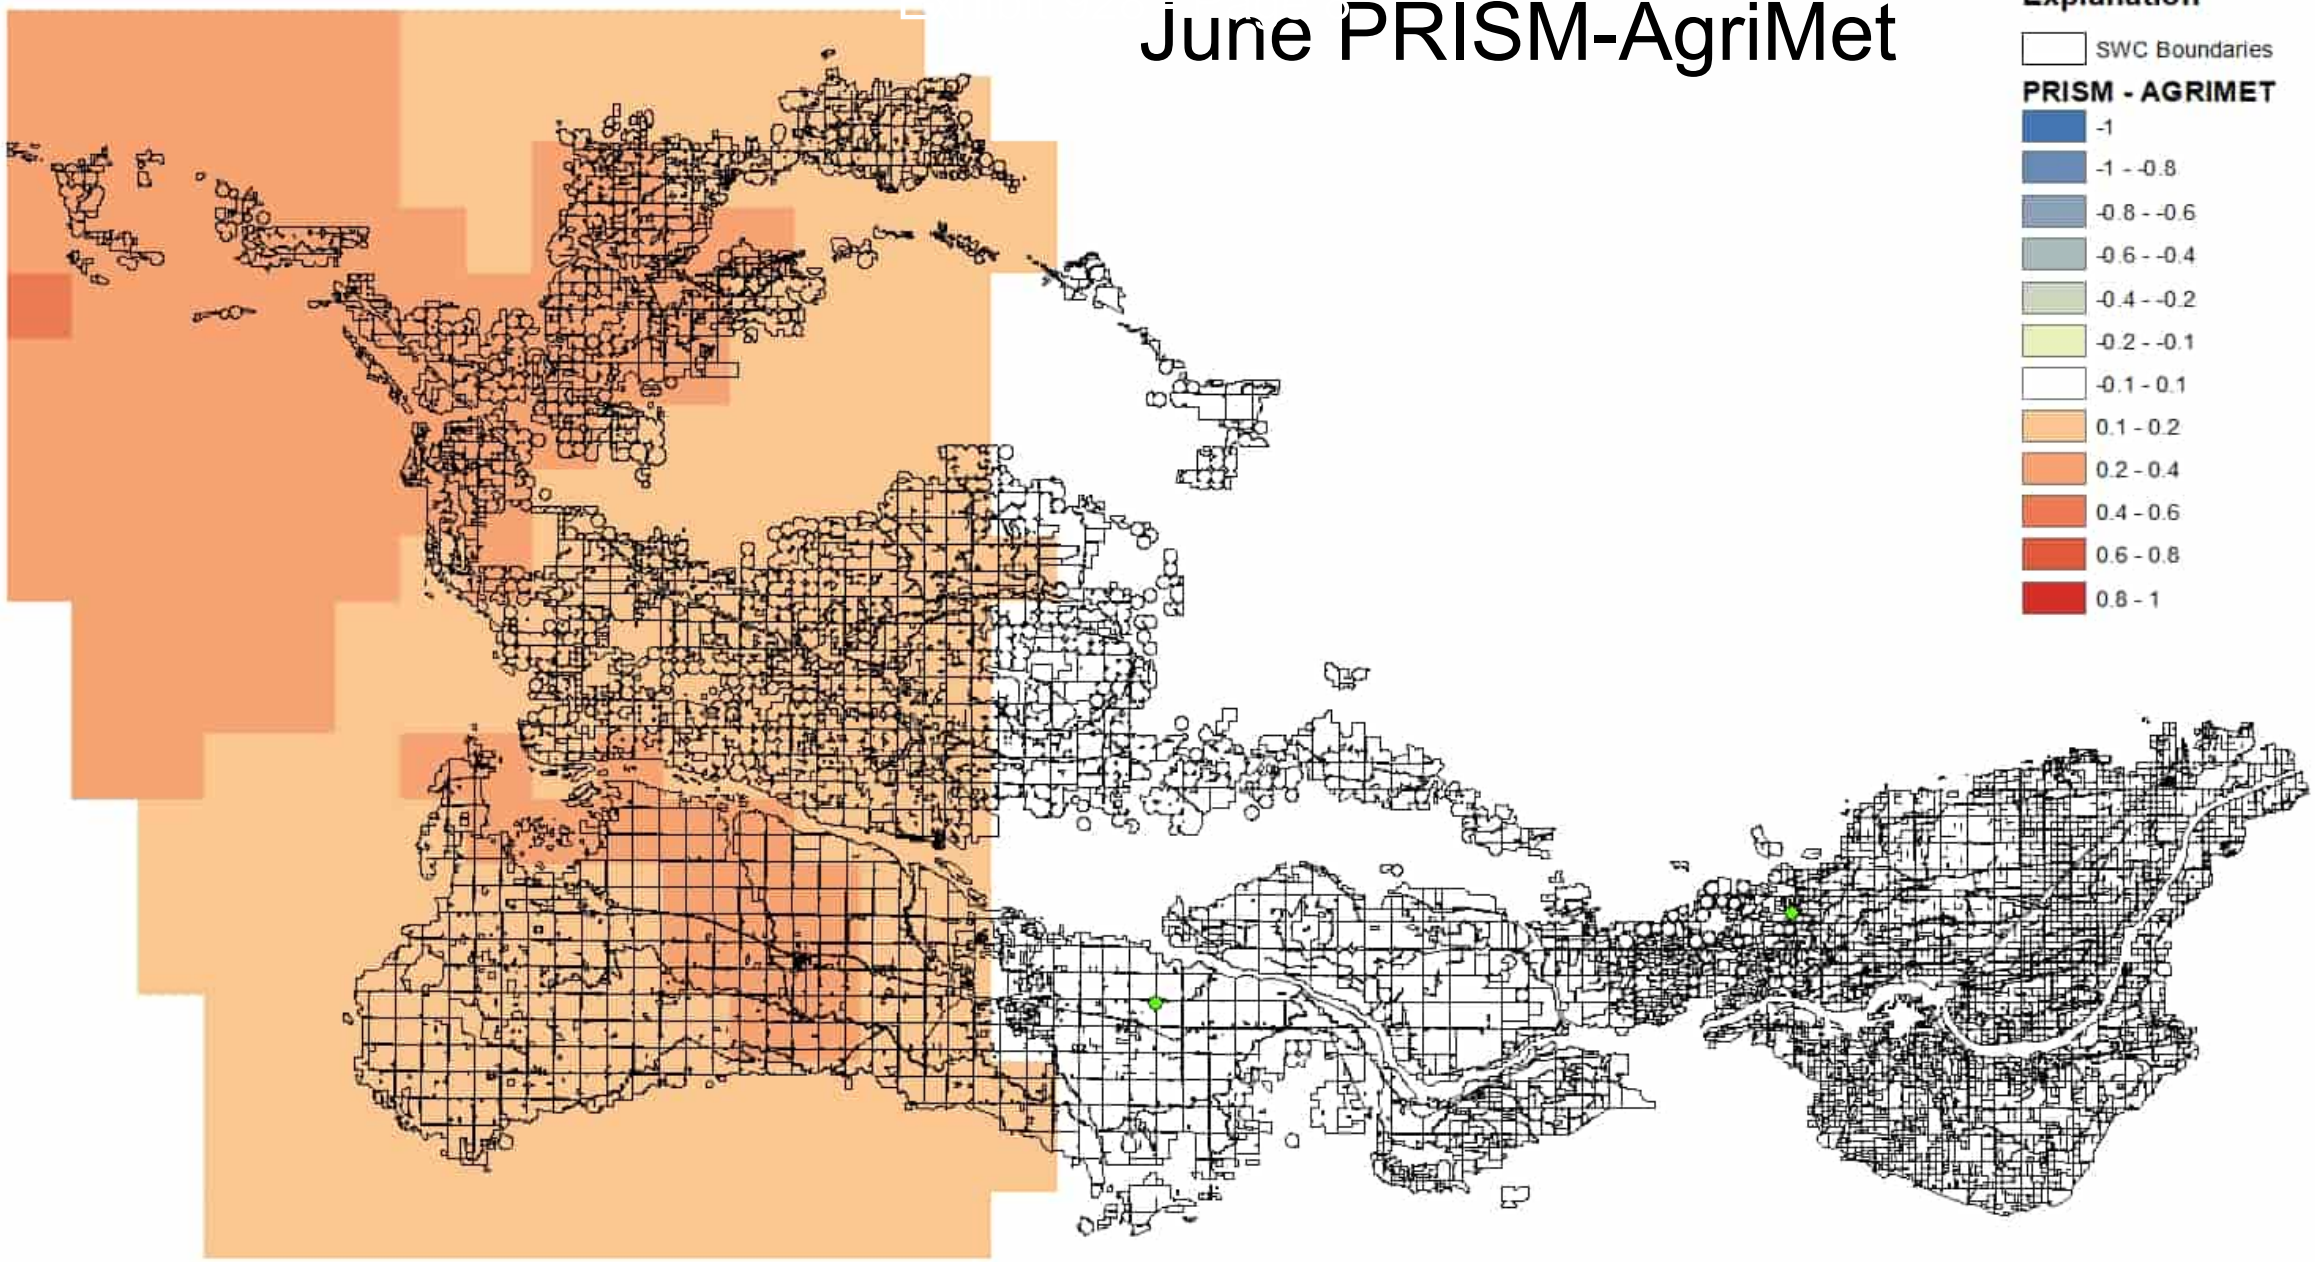
PRISM – AgriMet Difference Analysis for 2021

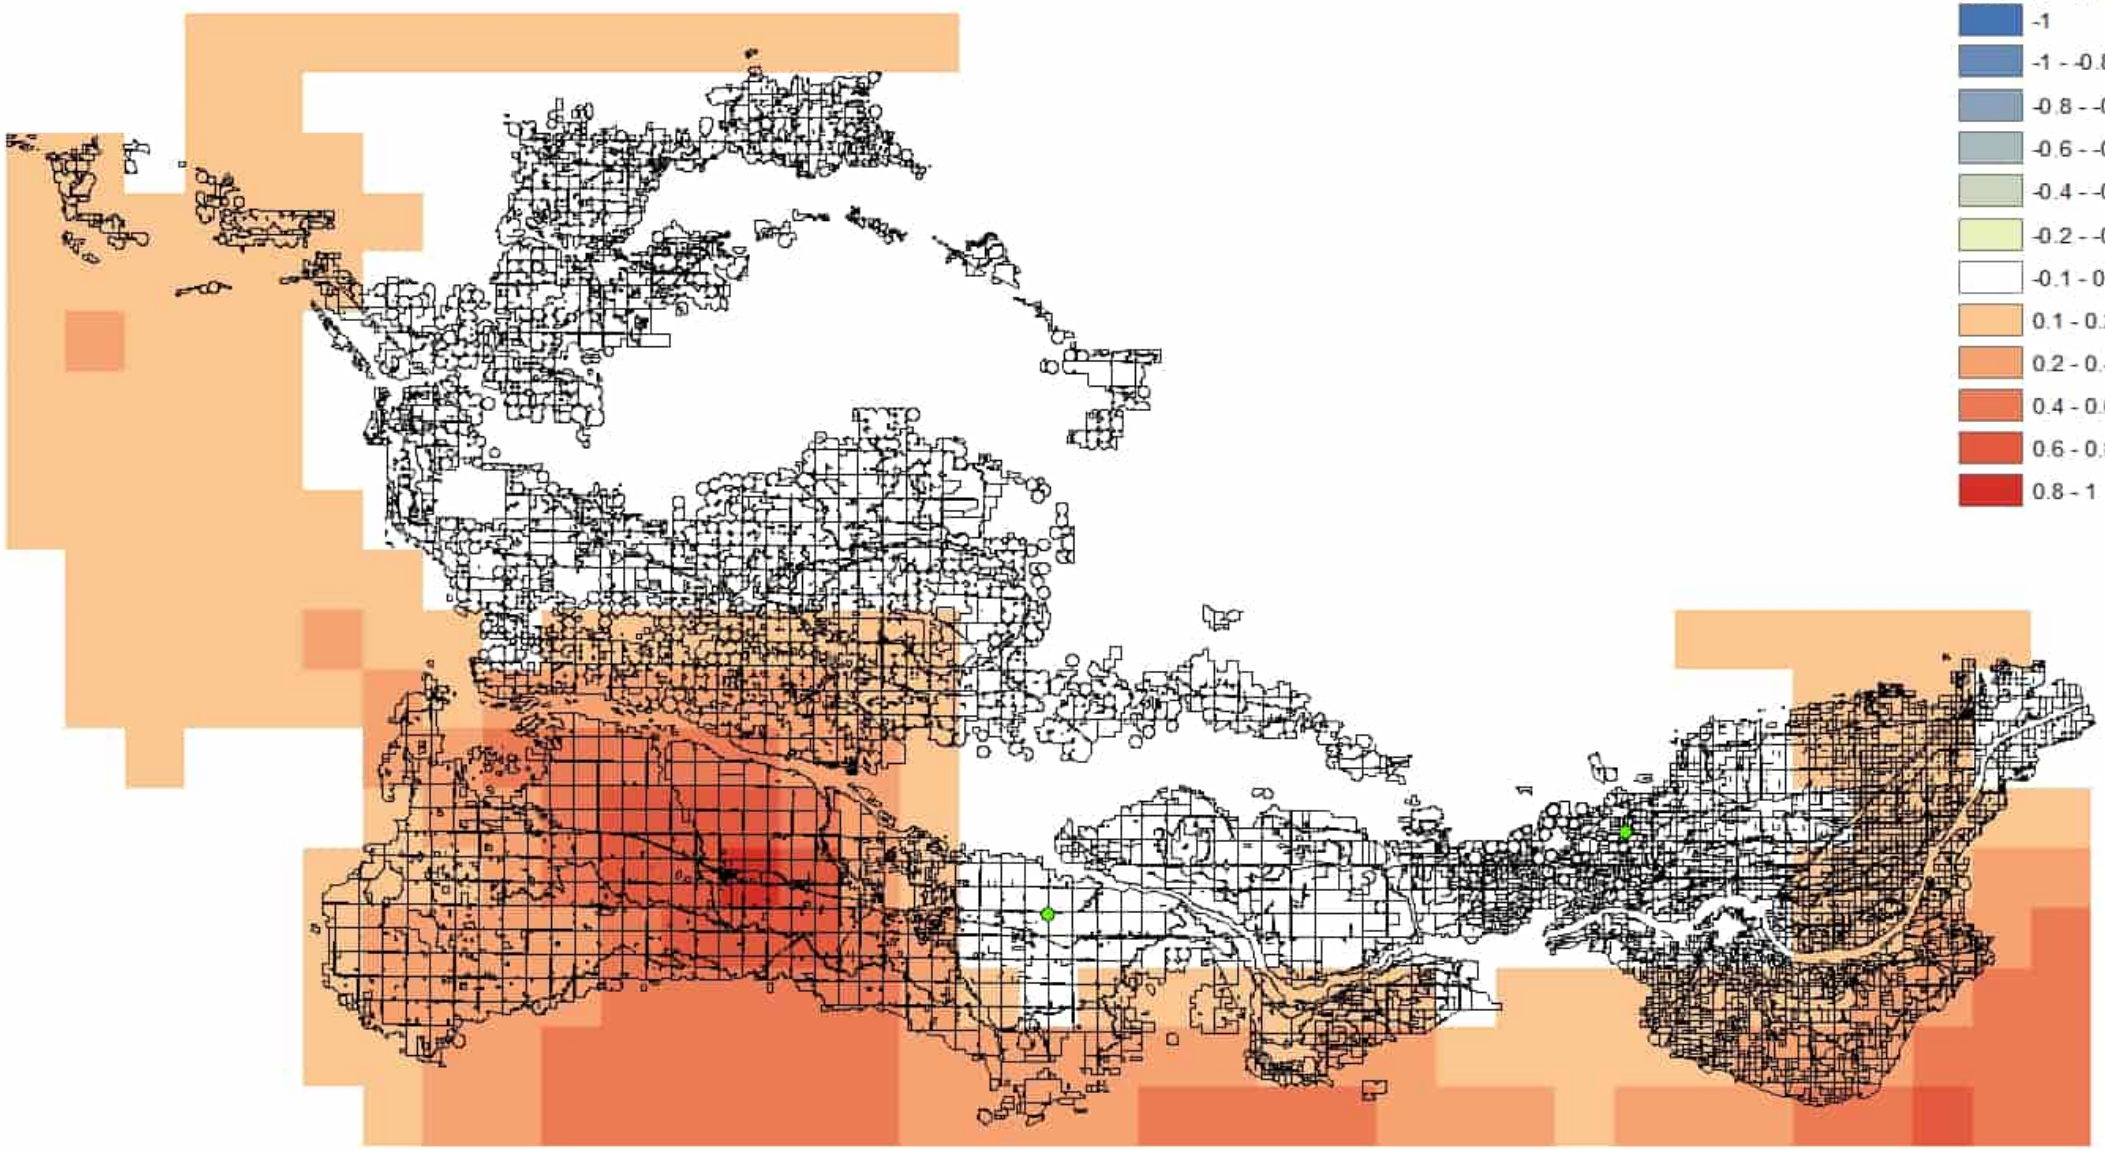


PRISM – AgriMet Difference Analysis for 2021

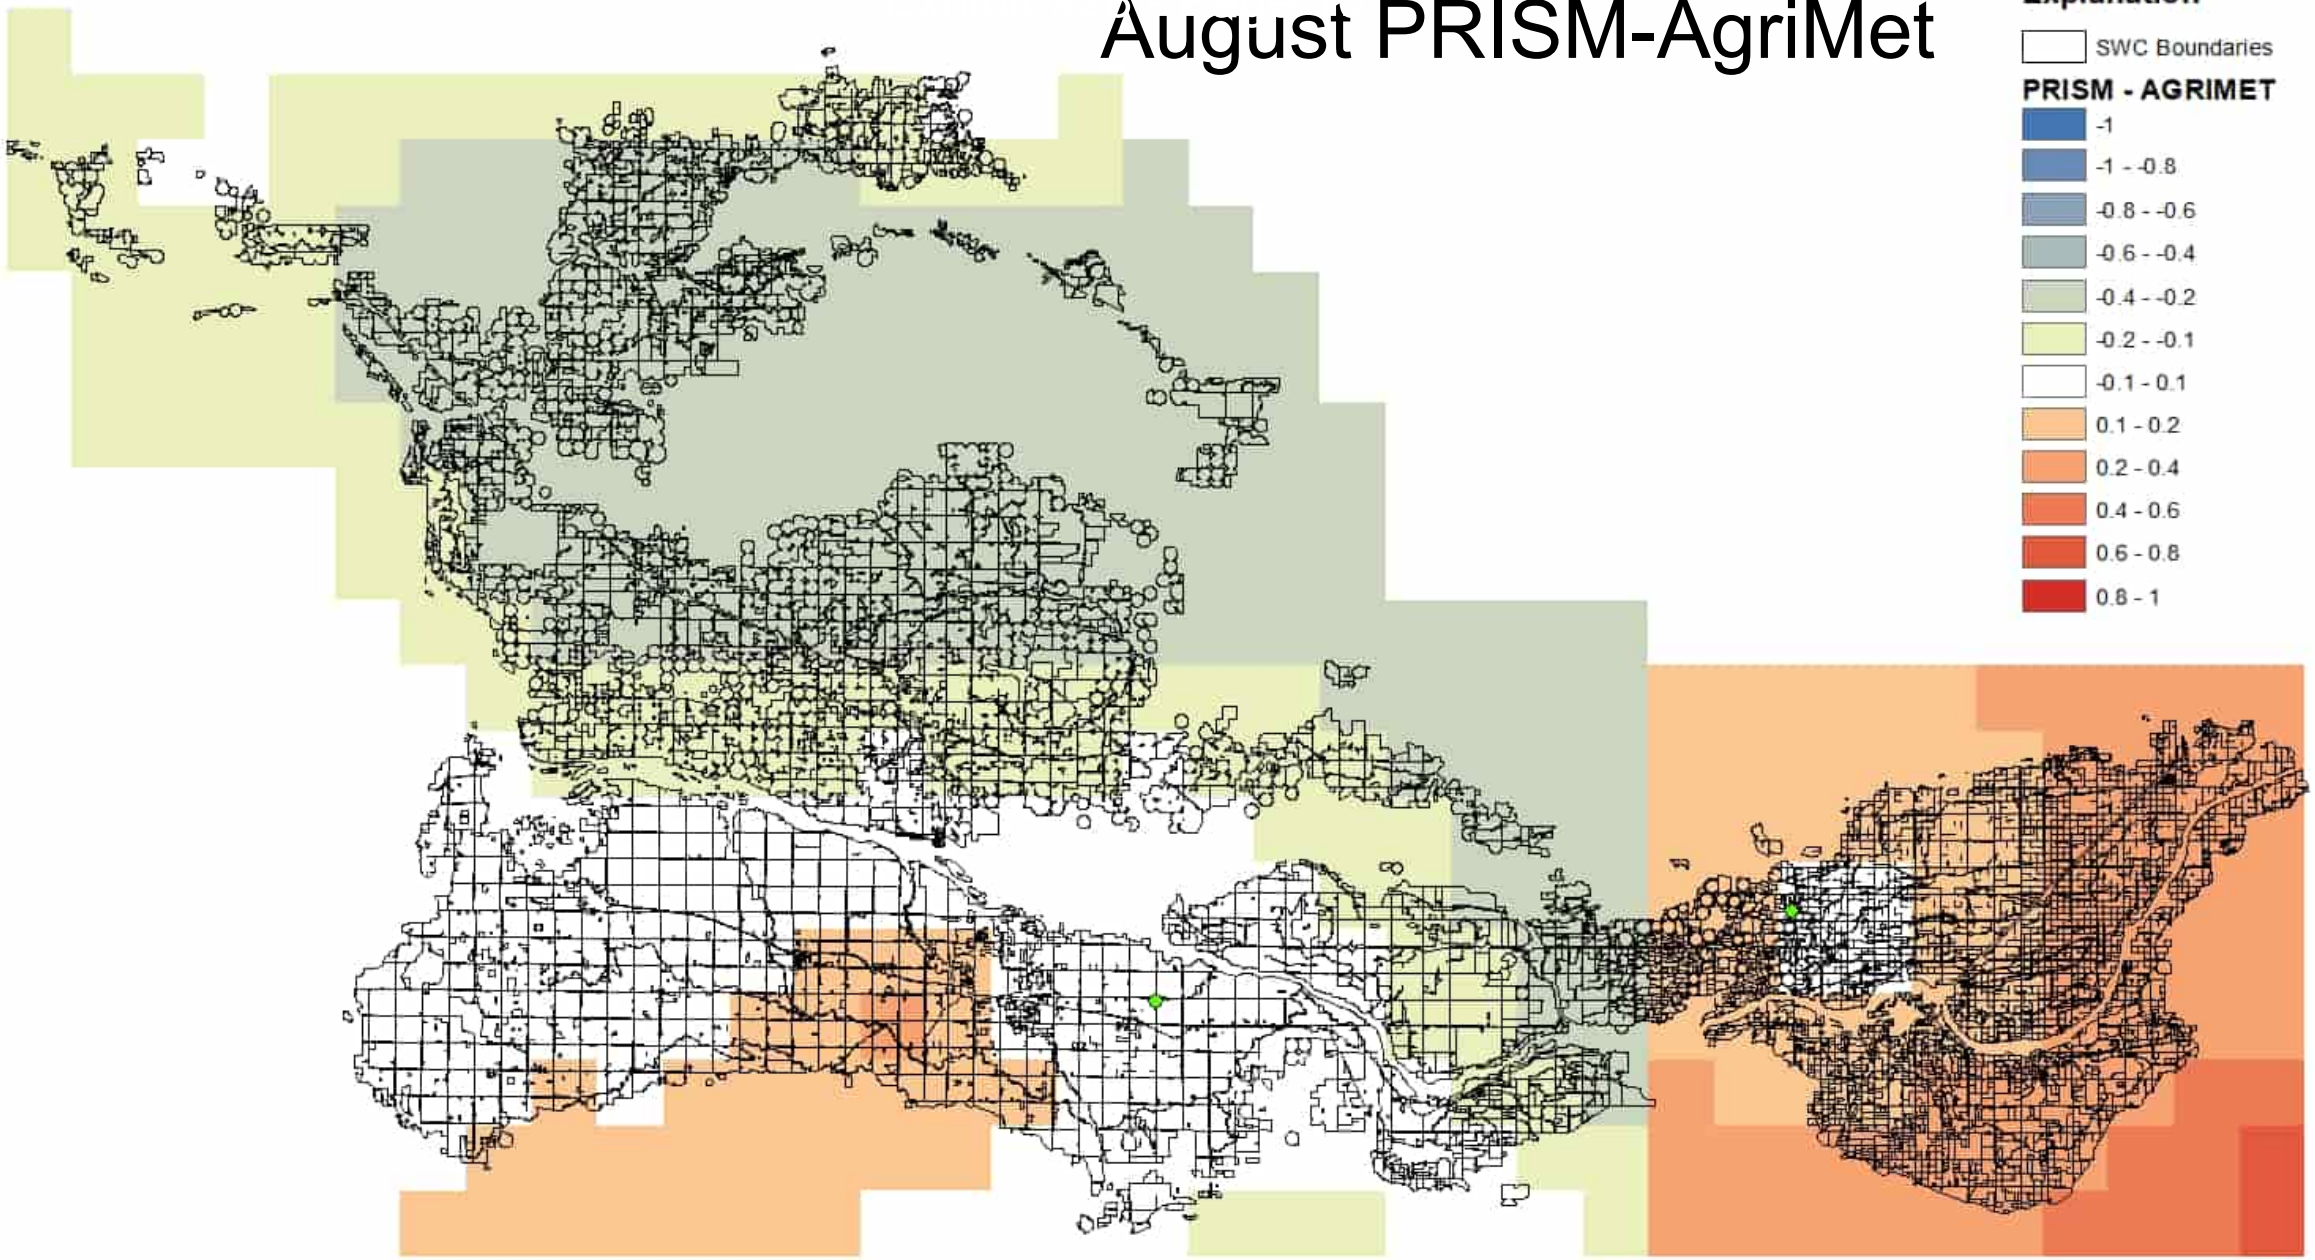
- Value (in inches) represent the difference between Effective precipitation from PRISM minus Effective Precipitation from AgriMet
- Same Effective precipitation method was used for both methods
- Twin Falls AgriMet was included for:
  - TFCC, AFRD2, NSCC, Milner
- Rupert AgriMet was included for:
  - A&B, Burley, MID
- Negative value in the graph below indicates Agrimet Effective precipitation was higher and would therefore decrease Crop Water Need more than PRISM for that month
- White background indicates the difference was between -0.1 and 0.1 inches



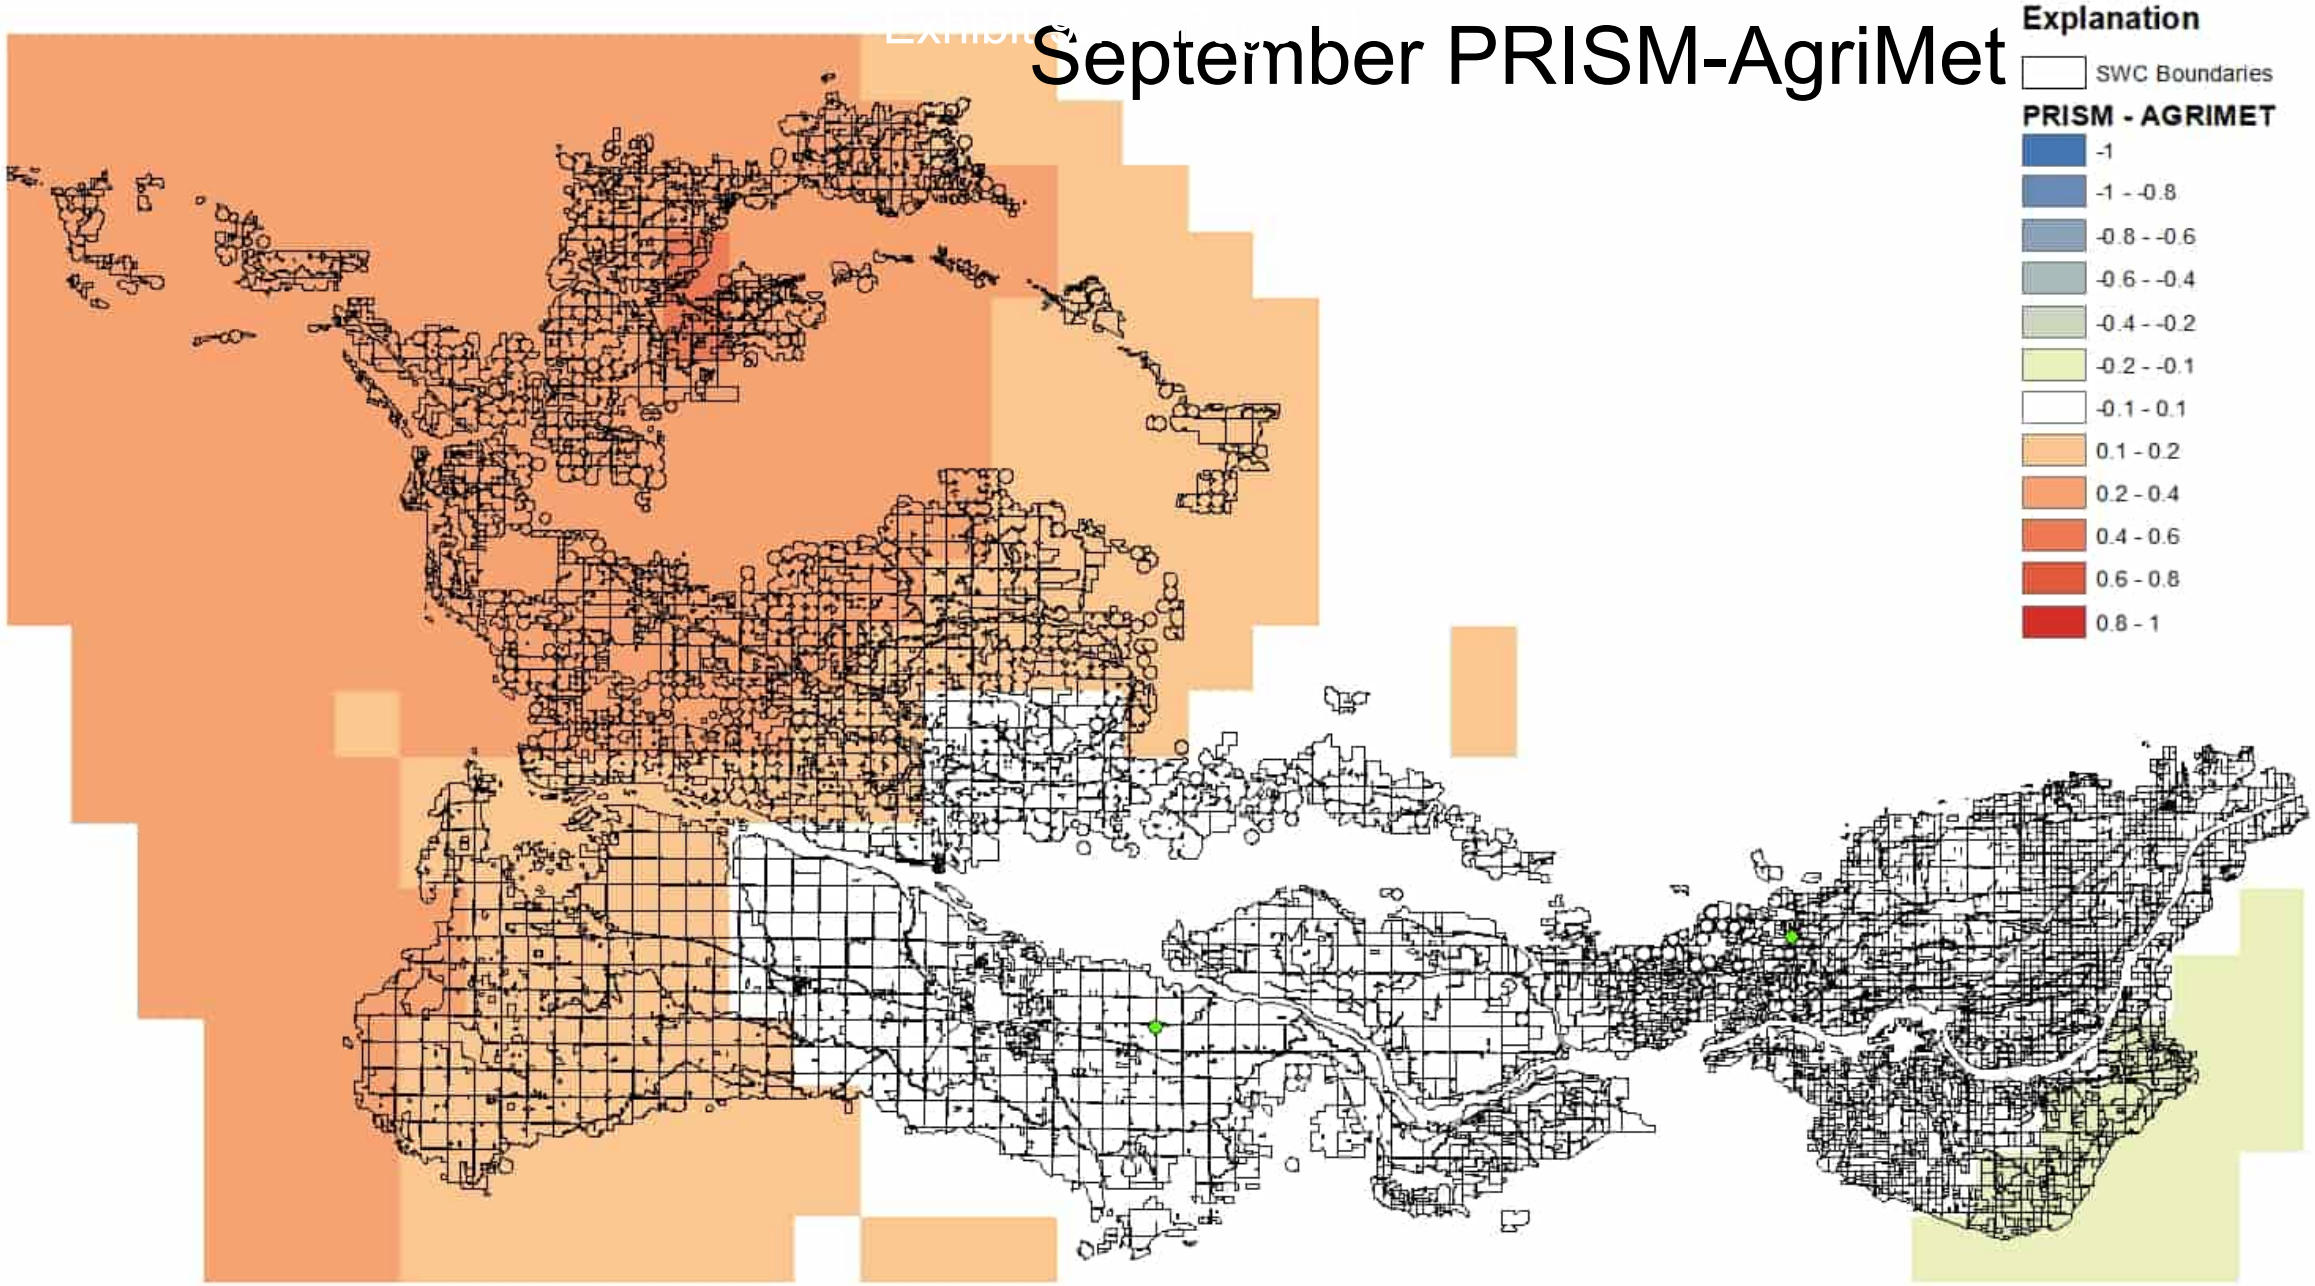
April PRISM-AgriMet



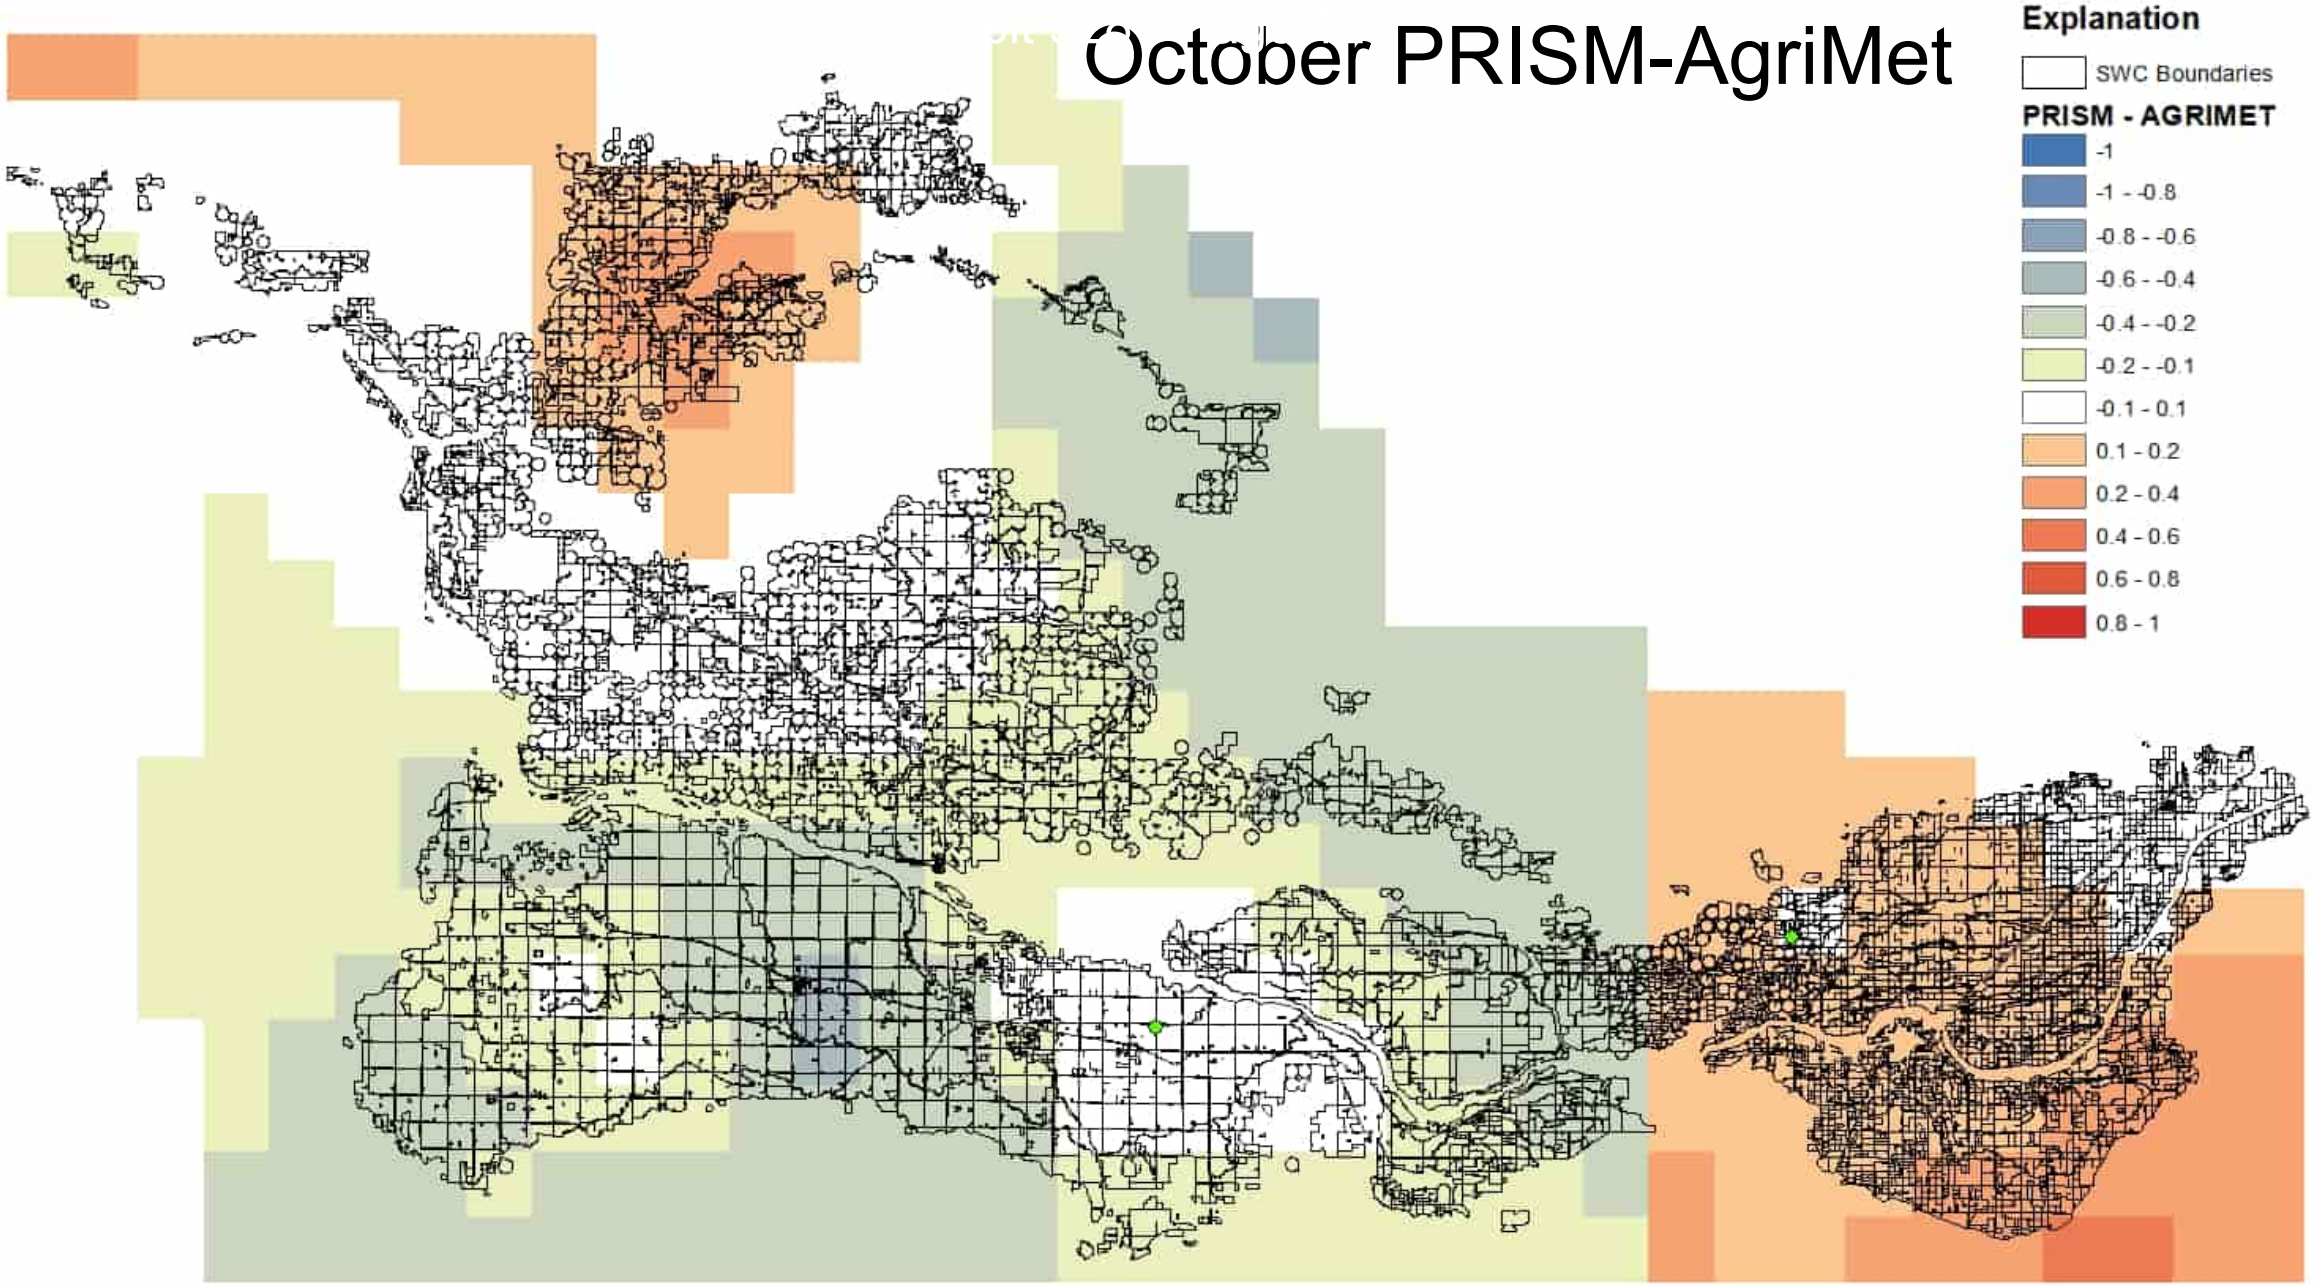
May PRISM-AgriMet



June PRISM-AgriMet



July PRISM-AgriMet



August PRISM-AgriMet

September PRISM-AgriMet

October PRISM-AgriMet

SWC Irrigated Acres

Current Method Crop Water Need

$CWN_{crop} = (ET_{crop}$- Effective Precipitation) * $Acres_{crop}$

- AgriMet ET
- Daily data from Rupert & Twin Falls stations.

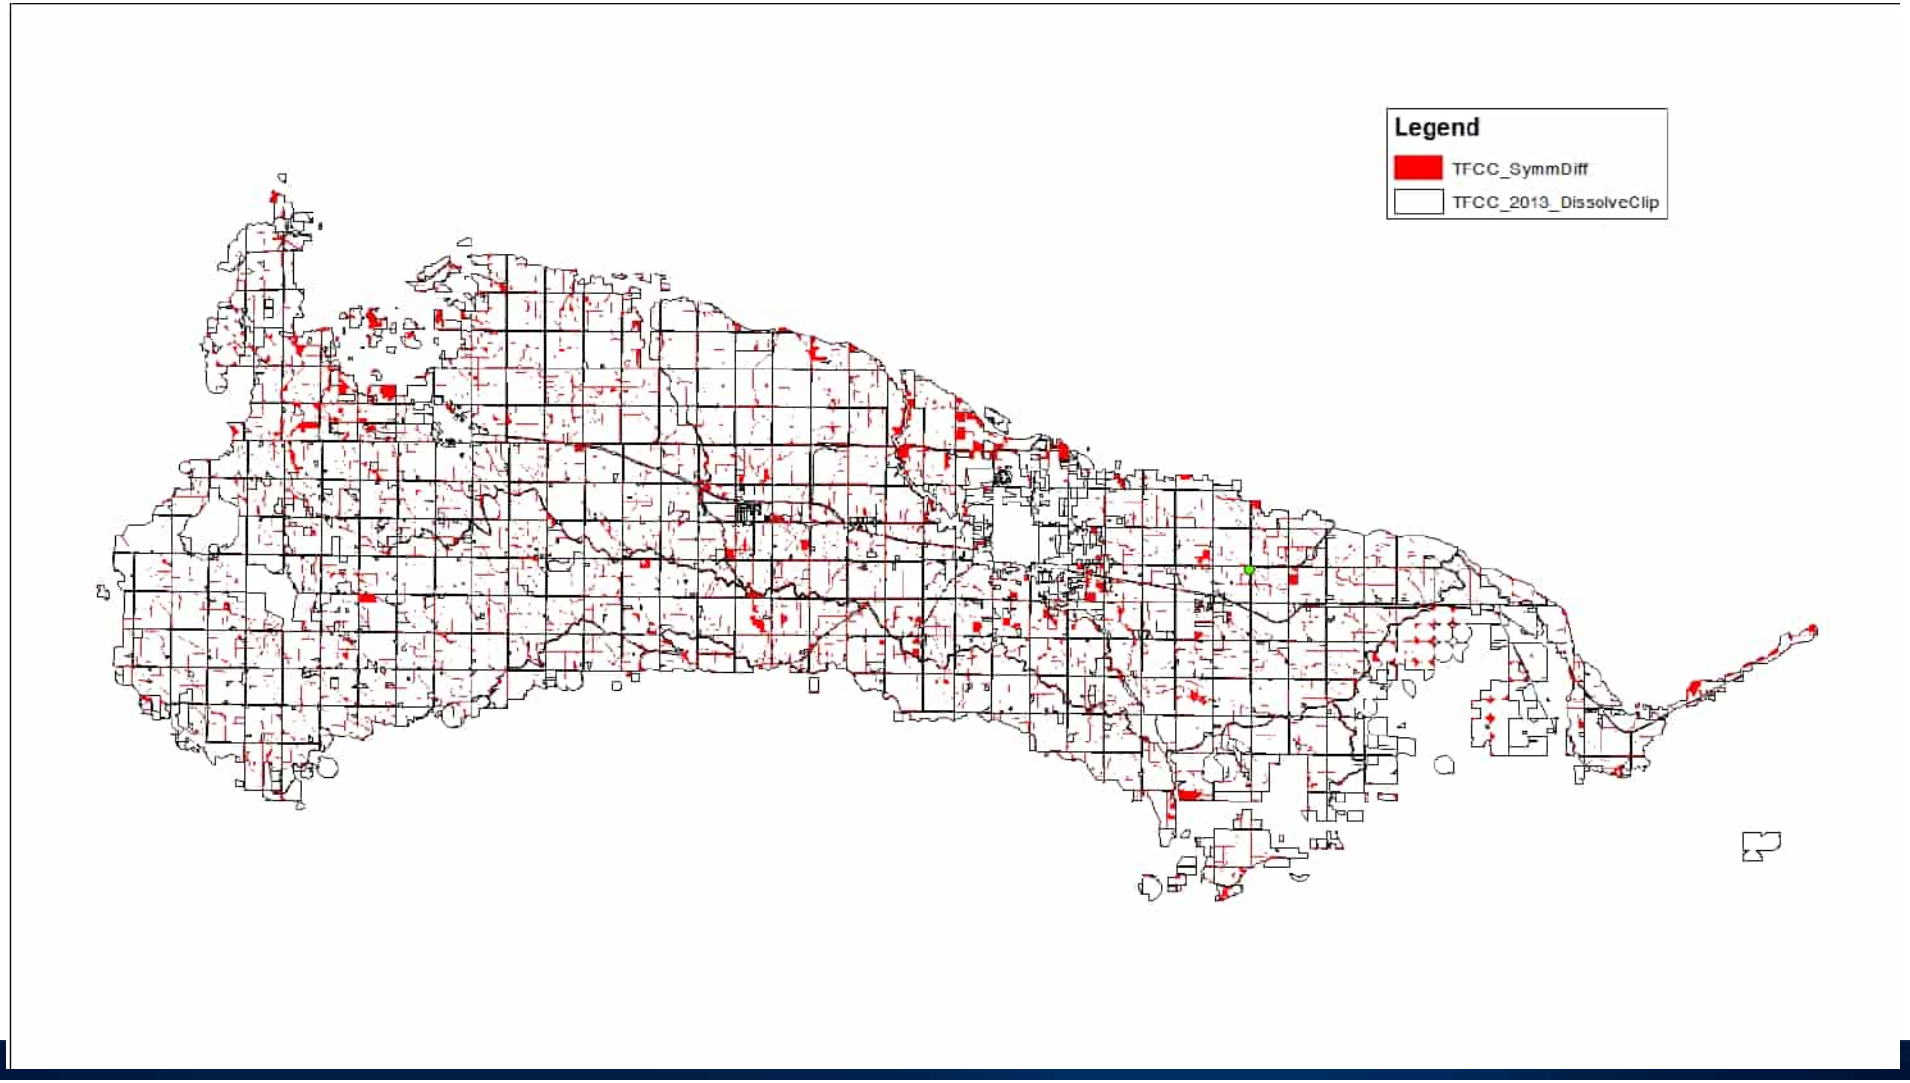
- AgriMet Precipitation
- Daily data from Rupert & Twin Falls stations.
- Calculate monthly effective precipitation.

- USDA Crop Data Layer (CDL)
- Remove data speckling and assign the majority crop in each polygon.
- ~~Remove non-irrigated land from CDL using the IDWR Irrigated Lands Dataset.~~
- Clip CDL to SWC service areas.
- Determine the 3-year average crop mix percentage
- Acres of Each Crop = Crop Mix % * Acres From Methodology

Proposed Method NRT METRIC Crop Water Need

CWN = (ET - Effective Precipitation) * Acres

- NRT METRIC
- Remove non-irrigated land
- Normalize “ET – Effective Precipitation” to AF/Acre for each SWC member



- Irrigated acres from methodology

- Oregon State University Prism Precipitation
- Calculate monthly effective precipitation

Methodology Reference

- Irrigated Acres (Page 35 of Methodology)
  - Step 1:
    - Department staff will review submitted shapefiles and modify them as necessary to ensure that:
      - (1) the total acreage count does not exceed the decreed number of acres;
      - (2) all of the irrigated land is located within the decreed place of use; and
      - (3) acres are not counted more than once due to overlapping polygons within a shapefile or between shapefiles submitted by different SWC members.
    - Because the SWC members can best determine the irrigated acres within their service area, the SWC should be responsible for submitting the information to the Department.
      - If this information is not timely submitted, the Department will determine the total irrigated acres based upon past cropping patterns and current satellite and/or aerial imagery.
      - If a SWC member fails or refuses to identify the number of irrigated acres within its service area by April 1, the Department will be cautious about recognizing acres as being irrigated if there is uncertainty about whether the acres are or will be irrigated during the upcoming irrigation season.

Pacific Northwest Project
Technical Information Memorandum

DATE: May 30, 2023

TO: Mr. Gary Spackman, Director, IDWR
SE Idaho Groundwater District Boards-Managers

FROM: Darryll Olsen, Ph.D., Pacific NW Project*

SUBJECT: Supplemental Technical Memorandum for:
Policy White Paper Review for Economic Impacts Surrounding Water Right-Water Supply Restrictions to Groundwater Appropriators, Irrigation Sector Operations

---

Given the pending decisions affecting groundwater and surface-water irrigation allocations in South-East Idaho, the Pacific NW Project is providing supplemental information to the initial Policy White Paper (January 2023), further highlighting key economic impacts associated with water right-water supply curtailments/regulations affecting groundwater irrigators (see attached Table 1).

This information should better inform water managers. the IWRD Director, Gov. Brad Little, Idaho legislators, and other key parties (including the media/press) about the probable economic impacts affecting water supply curtailments to South-East Idaho groundwater pumpers with junior appropriation water rights. At best, the economic impacts should be viewed as the assets at risk to Idaho and the five-county study area.

The IDWR is taking a very cautious approach to protecting surface water right allocations;[1] so being, an equally cautious approach to recognizing, and appreciating, probable economic impacts to groundwater allocations restrictions should be employed as well. The regional/state economic impacts are very real, and they provoke the need to call for a workable course of action to deal with both groundwater and surface-water irrigation needs.

This Technical Memorandum raises the following questions:

1. What is the significance of Irrigated Agriculture or the Irrigated Agriculture Industry in Idaho and the primary project area?

3030 W. Clearwater, Ste. 205-A, Kennewick, WA
509-783-1623, DOlsenEcon@aol.com

[1] The IDWR relies on judicial/cultural review of definitions for "material injury" and "reasonable use" to formulate its initial 2023 water allocation rule. While the approach retains justification, it does not bar discretionary decisions by the IDWR Director. Current above average flow conditions could be given greater deference in determining the difference between a "material injury" versus an "empirical injury," where reduced water supply impacts cannot be physically observed on the ground.

2. What does the current water supply situation in SE Idaho suggest (per Table 2 attached)?

3. How is "material injury" to senior water rights considered versus "empirical injury?" What does this mean for the current decision-making situation?

4. What types of economic impact measures and methods are used in this Technical Memorandum and the White Paper?

5. How are irrigated acreage impacts derived? What does this mean in terms of curtailed groundwater acres relative to surface supplies, acre-ft. and acres?

6. What does the economic impact analysis indicate affecting household income, revealed as direct and secondary (regional impacts)?

7. How should near-term versus long-term economic impacts be best understood?

8. What about water resources policy? What can the director do or consider given legal and conventional water resources management rules?

9. If *empirical impacts* are highly improbable, or difficult to measure, should that factor be given consideration by the IDWR director in determining reasonable protection for senior appropriator water rights? Does the weight of the probable economic impacts further support a "do no harm" approach?

10. The White Paper speaks to "internal" and "external" factors affecting groundwater and surface-water allocation conflicts in SE Idaho. What does this mean?

*Principal Investigator:

Darryll Olsen, Ph.D., Regional Planner/Resource Economist.

- About 35 years of experience preparing/directing all types of water resources economic impact projects and policy issues (Western U.S.).
- Principal economist for Argonne National Laboratory-FERC water resources project evaluations—hydro power, NED and RED impacts.
- Extensive economic evaluation work with Utah Dept. of Water Resources, water supply delivery projects; including water right change/transfers.
- Board Representative for Columbia-Snake River Irrigators Association; lead economic, technical, legislative, and litigation projects.
- Board Director, Badger Mt. Irrigation District (Ag. Irrigation, Domestic Irrigation-Household Water Service).
- Principal Author, RCW 90.80, Water Conservancy Boards in WA State; evaluated and/or approved hundreds of water right changes/transfers.
- Contributing Author, RCW 90.90, Columbia R. Basin Water Supply Act.

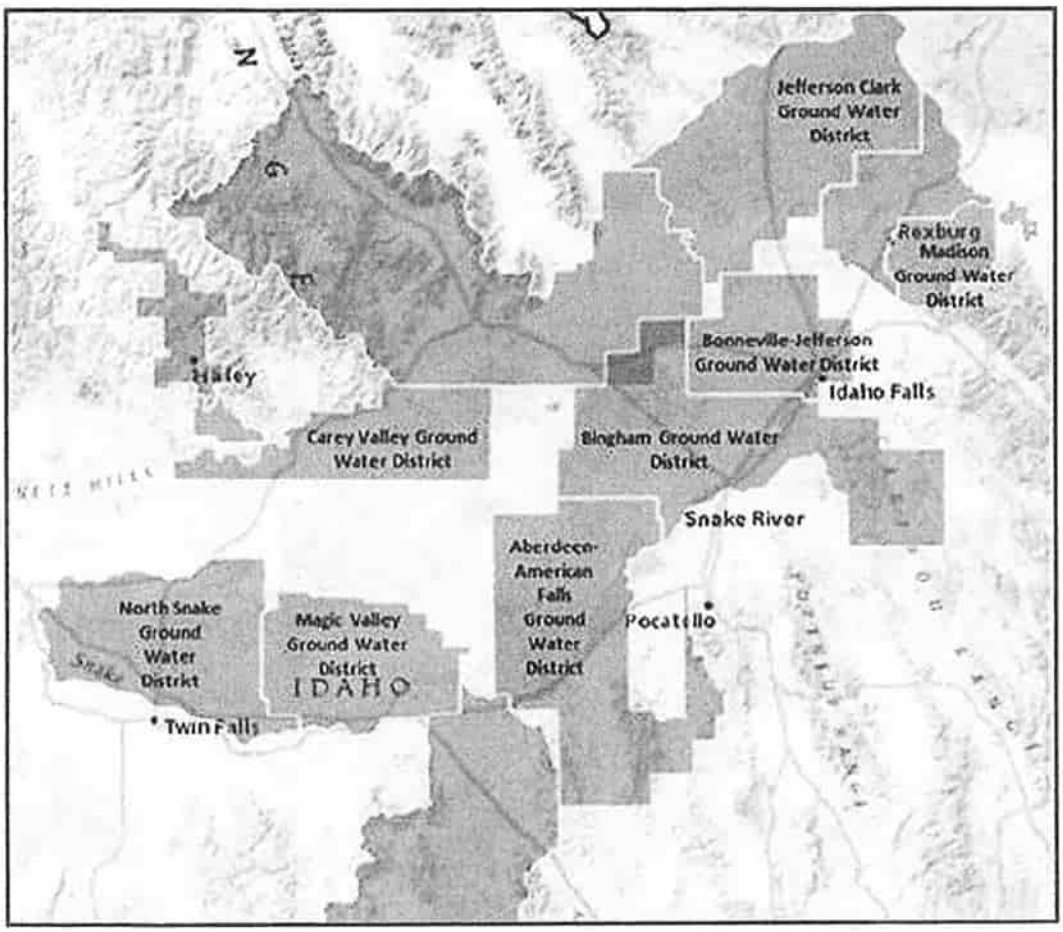
Sources: NOAA, Northwest River Forecast Center, Water Supply Forecast Listing, 5-27-2023; IDWR, Flows Forecast April 1, 2023.

Observations:



1) The estimated acre-ft./acre water demand/use for the Twin Fall Canal Company at 5.76 act-ft./acre, Total Supply, with forecast supply at 5.37 acre-ft./acre. Total irrigated acres are about 194,732.

This suggests that 3.5 acre-ft./acre could be net crop consumptive use, with 2.26 acre-ft./acre applied to carriage use/loss with some return flows; or about 40% of total dedicated supply demand.

2) For conversion to groundwater curtailment levels, it requires approximately 3 acre-ft./acre to supply 1 acre-ft. at TFCC. Conversion/impact rate is still under review for the Snake River Plain Acquifer.

Southeastern Idaho Water Resources Management Impacts

Surface-Groundwater Irrigation Demands

A Policy White Paper Review

Prepared By
Darryll Olsen, Ph.D.
Pacific Northwest Project

Prepared For:
Bingham Groundwater District
January 2023

In Summary

1. Idaho's Irrigated Agriculture Industry—Cannot be Replaced.

Idaho's Irrigated Agriculture Industry—composed of direct agricultural production, agricultural services, and food processing—sustains valuable regional, national, and international markets. It is a benchmark for agricultural producers throughout the world. State political leaders should appreciate that loss of any part of it cannot be replaced.

2. Irrigation Water Supply—the Big Picture.

Idaho's Irrigated Agriculture Industry does not exist in a geographical vacuum. Western Industry assets and the Irrigated Agriculture Industry are facing unprecedented water supply challenges. This is being exacerbated by climate change impacts, turning important Industry producers into *climate change refugees*. The Pacific Northwest retains a relatively stable water supply.

3. Surface and Groundwater Conflicts in Southeastern Idaho.

The water supply conflicts in Southeastern Idaho have evolved after decades of successful Industry growth. Conflict has revolved around changing conjunctive surface and groundwater supplies strained by increasing demands, and long-term drought. Without implementing new water management options, 150,000 acres of irrigated land will be in jeopardy.

4. Idaho's Irrigated Agriculture Industry—How Valuable Are We?

a. Idaho's Irrigated Agriculture Industry relies on about 3.4 million acres, with a farmgate value of about $6.4 billion.

b. The five-county Focus Area (Bingham, Bonneville, Clark, Jefferson, and Power counties), consists of about 843,000 acres, with a farmgate value of about $1.1 billion. "Target acres" within the Focus Area represents about 150,000 acres.

c. The statewide Industry provides about $8.8 billion in total, annual household income.

d. The Focus Area creates about $1.1 to $1.6 billion in total household income (regional-statewide impacts).

e. The irrigated land market value for 150,000 acres is about $862,000,000 to $1.7 billion, generating about $15-30 million in property tax revenues.

f. The loss of 150,000 acres would reduce household income by about $268 million.

5. Reducing Conflict—Action Items for the Idaho Legislature and Executive Office.

a. Pragmatic institutional, operational, and infrastructure measures—do exist.

b. State funding role—provide a 10-year "fixed" program for $175 million, for enhanced water management in the Focus Area.

6. Final Thoughts.

Southeastern Idaho's long-standing surface-groundwater conflict is best resolved by the state's Irrigated Agriculture Industry. Otherwise, less sympathetic interests will enter the picture.

Southeastern Idaho Water Resources Management Impacts
Surface-Groundwater Irrigation Demands

1. Idaho's Irrigated Agriculture Industry—Cannot be Replaced.

Idaho's Irrigated Agriculture Industry ("Industry") is composed of direct irrigated agriculture production, agricultural services, and food processing sectors. It has been developed across the span of three centuries, and it sustains regional, national, and international markets. It is a benchmark for agricultural producers throughout the world. State political leaders should embrace the reality that it cannot be replaced; nor should it be taunted by avoidable risks.

The pressing concern is on the Eastern Snake Plain Aquifer (ESPA) Area, where four of the groundwater districts are most directly affected, along with surface water irrigators who are part of the conjunctive water use, water supply regime (see Figures-Maps 1, 2, and 3 attached).[1]

For Idaho's elected leadership, three important factors should be better understood:

1) Climate change has significantly added to state water resources problems; and it has forced a future generation of Western production agriculture to turn toward the Pacific Northwest. This has some potential opportunities for the region and state.

2) The economic impact to the Southeastern Idaho Region is highly significant. Its prevalence should be respected, not taken as a given.

3) All pragmatic management measures must be employed to avoid a 150,000-acre plus impact to either surface or groundwater irrigators. The economic magnitude of such a predicament should make political leaders' heads spin.

So, a complex set of economic, technical, and ecological factors beg the questions of what can local water resources managers and state political leaders do to bring about pragmatic water supply-delivery management actions, and to what extent should state leadership accept fiscal responsibility to keep Idaho's Irrigated Agriculture Industry from being diminished?

Answering the technical question may require some realization that cultural change and new mindsets may bring benefits for all parties concerned. A second question suggests that a realistic fiscal criterion should be adopted to justify legislative decisions to allocate capital budget funds.

2. Irrigation Water Supply—the Big Picture.

Idaho's Irrigated Agriculture Industry does not exist in a vacuum.

---

[1] The American-Falls-Aberdeen, Bingham, Bonneville-Jefferson, and Jeferson-Clark Districts; with key counties being Bingham, Bonneville, Clark, Jefferson, and Power.
Also see attached Figure-Maps 1, 2, and 3.

Western irrigation assets and the Irrigated Agriculture Industry are facing unprecedented water supply challenges, reflecting changing water demands and dwindling supplies. For better or worse, elected officials are now making "hard" predictions regarding what to expect from climate change in key agricultural regions.[2] This includes forecast changes in much of California, the Colorado River system, and within the Greater Columbia-Snake River Basin area.[3]

This change means Western Industry asset decisions must embrace that climate change is becoming an inalterable reality, and each Western sub-region embodies a different set of risks affected by increasing climate change trends. To some degree, water supply uncertainty can be reasonably understood among the different regions, and industry managers are now formulating future action plans.[4]

So, what does this mean, more specifically, for the situation in Idaho and the Eastern Snake Plain Aquifer (ESPA) Area?

There are both direct water supply-aquifer recharge impacts, and the increasing Western Industry desire to leave highly water-stressed regions in California and literally seek refuge in all parts of the Pacific Northwest. The first constraint is empirically internal to Southeastern Idaho—how should declining surface-groundwater supplies to be allocated, or managed? This is an added complication to a well-known dilemma.

The second concern is external in origin. The irrigation sector *climate change refugees* see a future—in Idaho, Oregon, and Washington. They are actively surveying the Greater Columbia-Snake River systems, seeking available water supplies—for their long-term future. This should not be necessarily perceived as a "threat" for the Industry, given more capital, joint ventures, and market outlets may be offered to Idaho irrigators.

3. Surface and Groundwater Conflicts in Southeastern Idaho.

Keep in mind that water supply conflicts in Southeastern Idaho represent decades of successful Irrigated Agriculture Industry growth. The Industry, and political leaders, should not lose sight of that fact.

The technical issue surrounds surface-groundwater conjunctive use along the Eastern Snake Plain Aquifer Area, stretching westward from the far corner of Southeastern Idaho to the Magic Valley Region (see Figure-Map 3 attached). Since the 1950s, groundwater pumping has operated with surface water diversions. Aquifer recharge has been, and is, derived from surface water flows

---

[2] Such as, recent changes to reallocate the Colorado River system, significantly requiring water "conservation" actions in major irrigated agriculture regions like the Imperial Valley and Central Valley (CA). In effect, the Colorado Compact has been (is being) renegotiated.

[3] U.S. Bureau of Reclamation, USBR SECURE Water Availability in the West, U.S. Dept. of the Interior, WA-DC, January 2021; Bonneville Power Administration, BPA RMJOC-II Report, 2018; Office of Columbia River, Ecology, "Long-Term Water Supply and Demand Forecast," Olympia, WA, August 2022.

[4] This situation has been best characterized by Columbia-Snake River Irrigators association (CSRIA), "A White Paper Review, Climate Change and Western Irrigation Assets," August 2022, Kennewick, WA.

from the Upper Snake River system, from tributary seepage, and incidental recharge from surface water conveyance systems. The surface water flows are protected as senior water rights, whereas the groundwater flows depend on more junior vintage rights. The groundwater "return flows" re-enter the Snake River, where it is used by surface water irrigators in the Magic Valley Region (see Figure-Map 3).

The most immediate Snake River reach area being affected by groundwater pumping is north of American Falls Reservoir, including the five-county Focus Area. Significant groundwater development began in the early 1950s, continuing until a moratorium in 1992. Through the 1980s, when roughly 90% of the groundwater irrigation had been developed, the river reach gains and aquifer levels held steady, peaking in 1985. Extended drought periods in the 1990s and 2000s led to rapid declines, but readjusted to a reduced level since 2010, with varying fluctuation following precipitation trends (see attached Figure 4). This condition brings a great deal of uncertainty for irrigators.

Both surface and groundwater managers now struggle to meet the demands of our prosperous Irrigated Agriculture Industry; the struggle coincides with low system operating budgets and the need for technological improvements to water delivery and application infrastructure. Opportunities to make better use of river flows to conserve groundwater exist, but infrastructure and management changes are fiscally out of reach for most surface water systems. Given the increasing severity of water supply shortages and the implementation time line for new infrastructure and management regimes, action needs to be immediately initiated. The public benefit from improved water resources management more than justifies an investment of public funds to expedite technological adoption, as is occurring throughout the west.

4. Idaho's Irrigated Agriculture Industry—How Valuable Are We?

The "Irrigated Agriculture Industry" depicts the direct agricultural production, agricultural services, and food processing sectors of the state and regional economies. These sectors are the economic engine of irrigated agriculture, affecting numerous other economic sectors; collectively, the sectors are the direct impact sectors, with indirect and induced impacts throughout the state and regional economies.

Economists and regional planners use various measures of economic activity to express the significance of industries or projects to an economy. For this White Paper, the preference is to target the value of the Irrigated Agriculture Industry in terms of state and regional household income; the regional income based on county income data attached to the irrigation acres, and further tied to estimates of irrigated acres that could be at greater risk for either surface water or groundwater sources.

Attached is the detailed Analysis Methodology applied to derive reliable estimates for making decisions affecting the surface and groundwater resources for the Southeastern Idaho Region under review here. Also attached are the more detailed analysis tables used to calculate the allocated irrigation production and resulting household income (Table 1 and 2).

The first step is to define irrigated agriculture production values.[5]

a. Direct Farmgate Production Value:

- At the state level, irrigated acres reside across 3.4 million acres.
- The direct farmgate production value is about $6.4 billion.
- At the multi-county level, about 843,000 irrigated acres are farmed.[6]
- This comprises about $1.1 billion of direct production value.

The second step is to estimate household income values (2020$):

b. State and Regional Annual Household Income:

- The statewide Industry provides about $3.5 billion in direct household income.
- Including all direct and secondary (indirect-induced) impacts, about $8.8 billion in household income is generated.
- At the multi-county level, the direct Industry income impact is about $624 million.
- Total regional income created is about $1.3 to $1.6 billion with an estimated regional to statewide impact range.
- The 150,000 target acres provide about $233-$291 million in household income. This could be attributable to either surface or groundwater acres (or both).

Another economic impact consideration is to estimate irrigated land values within the Focus Area. While it may be asserted that changes to land use could actually increase some land values, this is done at the expense of removing irrigated acres, losing a portion of this land value sector.

c. Land Market Value:

- The land market value within the multi-county area, for a targeted 150,000 irrigated acres is about $862 million to $1.7 billion, largely depending on whether land is distressed (lacks adequate irrigation water). This estimate also attempts to avoid irrigated lands that are in the "path" of new residential/commercial development.
- The market range accepted is about $10,500-$16,500 per acre, with an "index" value set at $11,500 per acre.

d. County Property Taxes:

- Irrigated property taxes reflect multiple assessment factors and outlay obligations. Based on an average weighted value for the counties, for the Focus counties, a range of about $15-30 million is estimated, for 150,000 acres (many assumptions at play).

So, the above economic value estimates, or impact measures, undeniable affirm the high impact of the Industry to the Focus Area and targeted irrigated acres at risk. No small deal.

---

[5] The production value for U.S. agricultures has varied widely during the past decade, see Figure 2 attached.

[6] The groundwater water Focus Area here is Bingham, Bonneville, Clark, Jefferson, and Power counties.

5. Reducing Conflict—Action Items for the Idaho Legislature and Executive Office.

State legislators and the Executive Office are no strangers to difficult economic and social issues. Their constituents are often eager to throw to them seemingly intractable problems. Some may argue that the situation cannot be successfully resolved. But that is not the case.

a. Administrative and Infrastructure and Management.

- The state of Idaho retains a relatively benevolent water code, where loss of water rights (relinquishment) can be avoided under conservation actions, water right leases for change/transfers, and water right mitigation measures. This may involve changing some cultural norms, but it does not involve loss of water rights or water access to effectively farm crops.

- Even more important, the Director of the Idaho Department of Water Resources (IDWR) wants to work with the Industry, not against it, to reach satisfactory solutions.

- The surface and groundwater right irrigators *still have* a viable list of operational measures that can be employed to improve water distribution system management and on-farm water application efficiencies. This is fortunate.

b. How Much Should the Legislature (and Irrigators) Spend?

- The legislature, and junior water right holders, should assume fiscal responsibility for meeting new water management objectives. It could be argued that several hundred-of-millions of dollars in land values are on the table, and that should influence what is deemed to be acceptable to spend. It sets a higher range bar to judge the value of expenditures.

- Establishing a "fixed" time horizon for implementing a plan is very important. Senior and junior water right holders cannot "horse around" with uncertainty. That timeline and task protocol schedule must be determined soon, and religiously held firm.

- A recommendation needs to be made. It would be appropriate to establish a ten-year implementation schedule, with a $175 million budget, for varying appropriations each year. The $175 million is approximately one-tenth of the land market values within the five-county area.

- Improved distribution system management should be a priority in the stressed river reaches of most direct need—specifically in the areas north of American Falls.

6. Final Thoughts.

The long-standing water supply issue in Southeastern Idaho needs to be settled by Idaho's Irrigated Agriculture Industry, before others enter the picture.

Western water law is under siege by interests that are unsympathetic to irrigated agriculture. Across the Western U.S., cries for greater regulatory intervention are being made by frustrated or bias state regulators, environmental groups, and Tribes. Even some irrigators are turning to courts to comply with, or modify, earlier vintage water supply agreements that can no longer survive under the effects of climate change or sustained irrigation water demands. And Idaho is no stranger to calls for added fish flows from Endangered Species Act (BiOp) inriver, fish flow targets.

Some of the regulatory and statutory proposals call for a complete overhaul of state water rights, management, and regulation. Even from the University of Utah College of Law, comes a call for re-adjudicating existing water rights, to give priority to socio-ecological "needs." In Washington, the state's water management authority has proposed legislative recommendations, to restrict measures for water right change/transfers and marketing that do not address environmental justice and social equity issues (as defined by the state). This has been coined "Critical Water Theory," where all state administrative actions constrict or uncritically control water rights, particularly those in private sector hands.[7]

Idaho is unique in that junior and senior water right holders have usually sought a high level of collaboration, and they are working with a state water management agency that clearly wants to resolve problems for the Irrigated Agriculture Industry.[8] This period of grace may be short-lived, and a reasoned mindset may fade away or be disrupted by others.

[7] University of Utah, S.J. Quinney College of Law, "Climate Change and Water Law Scholarship," Utah Law Digital Commons, 2020; Water Resources Program, Ecology, "Trust, Transfers, and Water Banking Legislative Report," Draft Recommendations, August-September 2022, Olympia, WA.

[8] Some point to the Yakima River Basin, WA, Yakima Integrated Plan (YIP), as a "model" of collaboration. But most improvements to date are "ecological" in nature, and the most significant water supply mitigation for irrigators has come from direct irrigator development of access to "dead storage" in the upper basin. The overall YIP is multidecadal in structure and costs billions of dollars.

Analysis Methodology for State-Regional Irrigated Agriculture Industry Household Income Impacts[9]

There exist ample data and modeling experience to analyze the impacts of Irrigated Agriculture to the state and regional economies. The basic approach used in this White Paper is to determine income impacts relying on: 1) Agricultural Census-NASS and Economic Research Service data; 2) U.S. Bureau of Economic Analysis (BEA) data sets for income by place of use and detailed sectors; and 3) available state and regional input-output and IMPLAN model multipliers for the Irrigated Agriculture Industry (agricultural production, agricultural services, and food process sectors).

While several descriptive, irrigation/agricultural economic statistics are often cited, the Industry's contribution to household income is rarely expressed in total household income impacts at either the state or regional level. This type of estimate requires estimating the allocation of direct production to irrigated agriculture, and the use of input-output analysis multipliers (usually) to estimate aggregated industry sector secondary impacts (direct, indirect, and induced impacts from the Industry). The resulting estimates likely fall within an acceptable range.[10]

In summary, the steps used to calculate household income from the Industry are described below:

- By state and county, total agricultural production values (2017-18) are obtained from the Ag. Census-NASS data, and Economic Research Service for annual data series (where available). These data sources breakdown crop/livestock production value contributions by commodities and specialty crops by state/county.

- The NASS data sources have data (20017-18) for irrigated acres by state and farms, with and without irrigated acreage. Irrigation includes pasture ground for beef/livestock.

- The U.S production value (crops and livestock) did not increase between 2017 and 2021. Since that time, aggregate production value increased by about 30% (see Figure 5).

- Using the above data and related state sources, estimates of production value by commodities and specialty crop, bay state and counties, are prepared, that are allocated to irrigation lands (both primary and secondary production). This includes crop/livestock production.

- The estimated production value percentages linked to irrigated agriculture must take into account dry-land versus irrigation production, where no irrigation is used. There are no

[9] Also see Table 2 footnotes and analysis comments.

[10] This White Paper represents the fourth time that the Pacific NW Project has estimated Western Irrigated Agriculture impacts, as generally described herein. Consequently, greater confidence in the methodology has been obtained over time, including revised data assumptions and receipt of peer review comments from public and private sector economists (per previous analysis); nevertheless, all assumptions or analytical errors are solely the responsibility of the Pacific NW Project. The numbers and analysis presented are perceived as providing decision makers with useful information for water resources management in Idaho.

direct irrigation production data to make precise estimates, so qualitative or judgment-based assumptions must be applied, taking into account state-regional production data and conditions. The estimated irrigation-production allocations are presented in Table 1.

- An estimated percent of production value allocated to irrigated agriculture then can be applied to household income created by agricultural production, agricultural services, and food processing sectors (see Table 2). The allocations are combined to derive direct household income to the state and region (counties). These estimates are highly reliable, based on BEA 2020 income data.

- Economic sector linkages among the agricultural production, agricultural services, and food processing sectors are relatively direct and uniform; as such, the application of the production value estimates to direct household income among the sectors is considered a reasonable estimate as well. In particular, higher levels of income derived from irrigated agriculture (versus non-irrigated agriculture) are expected, and the impacts to agricultural services and food processing are usually higher as well.

- Using input-output model (IMPLAN and state sources where available) multipliers for the state and select region, value added (and income) multipliers have been calculated for the combined economic sectors of the Irrigated Agriculture Industry. The multipliers are then applied to the direct income estimates (see Table 2 and discussion therein). In previous studies the multipliers used here reflect several years of estimation and review, and the overall approach has been previously discussed with IMPLAN modelers and other conversant with I/O applications.

- The direct and secondary linkages among the economic sectors are relatively stable over time, although efficiencies in production and newly developed production products will increase the multipliers impacts. As such, it could be assumed that the multiplier levels considered here (VA multipliers and household income estimates) may be conservative. Future estimates would benefit from new IMPLAN modeling work that may marginally change the impact estimates.

Table 1. Estimated Farmgate Production Value--Total and for Irrigated Agriculture, 2018

Estimated annual household income impact for Multi-County Area: $1,550/irrigated acre, crop and pasture.
Estimated annual household income impact for Statewide Area: $1,940/irrigated acre, crop and pasture.
Estimated annual household income for impact of 150,000 acres multi-county impacts: $232,500,000.
Estimated annual household income for impact of 150,000 acres state-wide impacts: $291,000,000.

U.S. Bureau of Economic Analysis (BEA), Regional and Local Data Bases and Apps, multiple data bases for state and county NAICS sector data, for 2020 (2022). Household income data includes farm proprietor, labor income, agricultural services, and food processing. Generally cited as "BEAR Facts" data bases and apps (multiple BEA web site locations, updated annually..

NOTE: Food processing sector for Power County is a "place holder" estimate to avoid IRS disclosure issues; some corporate income is included in the state-county areas. Main access site initiated at: https://apps.bea.gov/regional/bearfacts/, and sites referenced therein (includes state GDP and household income).

NOTE: Regional-state household income multipliers based on IMPLAN and state input-output modeling for multiple areas, including WA-ID-CA and the Columbia Basin areas focusing on Production Irrigated Agriculture industry (production agriculture, agricultural services, and food processing combined sectors). Multiple analyses where considered. The modeling runs were relying on 1998-2013 data; the intersector linkages remain relatively stable over time, as such the multiplier estimates used here are deemed reasonable for the needs of this Policy White Paper. We note that the concentration of food processing for the counties is high, and this sector retains higher multiplier values, than the production irrigated agriculture sector alone. We note as well that more recent impact analyses for irrigation manufacturing and services suggest higher range multipliers.

For IMPLAN modeling purposes, the above sectors are combined (direct impact), with indirect-induced impacts calculated from the joint sector modeling (Pacific Northwest Project approach). Previously working with IMPLAN group modeling staff and regional IMPLAN modeling economists, this review considered both income and value added (VA) multiplier use, recognizing structural differences. Nevertheless, the VA multiplier is applied here in an attempt to reflect the full household income impacts associated with labor income, all forms of proprietary income, and associated land income (rent), and taxes contributed to additional statewide income. In effect, all income. The U.S. BEA Regional Input-Output Modeling System, RIM II Guidebook, defines value added income as generated from compensation, payments to government (taxes), and investment returns--essentially all income impacts.

Regional impact sources include: Pacific Northwest Project, "The Economic Importance of Western Irrigated Agriculture, 2015," White Paper Review, Prepared for the Family Farm Alliance, Kennewick WA (available at CSRIA.org and FFA web site). Statewide VA multipliers in the 2.0 to 2.5 range.

Office of Financial Management/UW, "The 2012 Washington Input-Output Study," OFM-Olympia-WA, Forecasting & Research, 2021. Used by State of Washington for estimating biennial budget impacts, multipliers for agriculture and food processing (employment multipliers at 1.5-3.3, often associated with income multipliers).

Entrix, Inc., "Economic Contribution of Agriculture Irrigated by the Columbia Basin Project," Prepared for the Columbia Basin Irrigation Dists., 2010, Entrix, Inc, Vancouver, WA. Multi-County and Statewide VA multipliers in the 1.8 to 2.4 range (some multi-state "linkage" indicated).

Columbia-Snake River Irrigators Association/IRZ Consulting, "Economic Impacts from Irrigation Development, East-Low Canal, Columbia Basin Project," Prepared for Office of Columbia River-Adams County, CSRIA, Kennewick WA 2013. (Regional and Statewide VA multipliers in the 1.5 to 2.0 range.

Congressional Research Service, "California Agricultural Production and Water Use, CRS, WA-DC, 2015. Statewide employment multipliers estimated at 2.2, usually associated with income multipliers.

Minnesota IMPLAN Group, Inc., "2004-2007 WA State IMPLAN Modeling Data Multipliers Reports," MIG, Stillwater, MN, 2007. Agriculture and food processing VA multipliers in the 1.4 to 2.4 range, not including dairy processing.

Numerous technical articles on I/O Model multipliers, such as Irrigation Association, "Economic Impact of the Irrigation Services Industry," 2021, IA. National employment multipliers in the 2.3 range (usually associated with income multipliers).

IMPLAN Blog, Understanding IMPLAN Multipliers, 2020, IMPLAN, Blog.IMPLAN.com, and other regional economic impact articles on internet sites.

Table 3. Estimated Market Irrigated Land Values and Benchmark County Property Tax Values

County Area	Market Values for 2018-2022 Sales, $/Acre Estimated Range $	Est. Index Value	Focus Area Acres	Total Est. Value	Land Value 50% Imputed Use Value	Est. Tax Rate Per $100 Taxable Value	Est. County Tax Revenue @ 100%	Est. County Tax Revenue @ 50%
Multi-County Area	$10,500-16,500	$11,500 (weighted est.)	150,000	$1,725,000,000	$862,500,000	1.75%	$30,187,500	$15,093,750
Bigham						2.16%	—	—
Bonneville						4.60%	—	—
Clark						1.03%	—	—
Jefferson						1.63%	—	—
Power						2.21%	—	—
TOTAL:	$10,500-16,500	$11,500 (weighted est.)	150,000	$1,725,000,000	$862,500,000	1.75%	$30,187,500	$15,093,750

Estimated market value range indicates $10,150-16,500 per acre. Approximately 50 market transactions reviewed for the 2018-2022 period.
Irrigated transactions reviewed as land with some infrastructure included (irrigation, farm buildings), no residential structures.
Irrigated transactions reviewed as land not in development path of existing communities and commercial development (location proximity considered).
Estimated irrigated land values above assume adequate crop water duties; index value should be considered relatively conservative estimate, given active demand for agricultural lands (for various production needs).

IN THE DISTRICT COURT OF THE FOURTH JUDICIAL DISTRICT OF THE STATE OF IDAHO, IN AND FOR THE COUNTY OF ADA

IDAHO GROUND WATER APPROPRIATORS, INC., Petitioner, vs. IDAHO DEPARTMENT OF WATER RESOURCES, and GARY SPACKMAN in his capacity as the Director of the Idaho Department of Water Resources. Respondents.	Case No. CV01-23-13173 **NOTICE OF LODGING THE AGENCY TRANSCRIPT AND RECORD WITH THE AGENCY**
IN THE MATTER OF THE DISTRIBUTION OF WATER TO VARIOUS WATER RIGHTS HELD BY AND FOR THE BENEFIT OF A&B IRRIGATION DISTRICT, AMERICAN FALLS RESERVOIR DISTRICT #2, BURLEY IRRIGATION DISTRICT, MILNER IRRIGATION DISTRICT, MINIDOKA IRRIGATION DISTRICT, NORTH SIDE CANAL COMPANY, AND TWIN FALLS CANAL COMPANY	

TO: THE DISTRICT COURT AND THE PARTIES OF RECORD

In accordance with I.R.C.P. 84(j), YOU ARE HEREBY NOTIFIED that the agency record and transcript, having been prepared pursuant to I.R.C.P. 84(f), (g), and (i), are lodged with the Idaho Department of Water Resources for the purpose of settlement.

A copy of the agency transcript and record filed with the Department have been uploaded to the Department's website. The parties may visit https://idwr.idaho.gov/legal-actions/district-court-actions/igwa-v-idwr-cv01-23-13173/ and follow their browser's document download procedure to obtain a copy of the agency transcript and record after expanding the accordion labeled "Agency Transcript and Record" and clicking on the PDFs titled "Agency Hearing Transcript on Appeal" and "Agency Record on Appeal" and the zipped file titled "Officially Noticed Documents."

The parties have fourteen (14) days from the date of this notice to file any objections to the transcript and record. The agency's decision on any objection timely filed along with all evidence, exhibits, and written presentations on the objection shall be determined by the agency within fourteen (14) days and included in the record. If no objections are filed within that time, the transcripts and record shall be deemed settled. Subsequently, the agency will lodge the settled transcripts and record with the District Court pursuant to I.R.C.P. 84(k).

DATED this 30th day of August 2023.

Attorneys for Idaho Ground Water Appropriators, Inc. (IGWA)

DISTRICT COURT OF THE STATE OF IDAHO

FOURTH JUDICIAL DISTRICT

ADA COUNTY

IDAHO GROUND WATER APPROPRIATORS, INC., Petitioner, vs. IDAHO DEPARTMENT OF WATER RESOURCES, and GARY SPACKMAN in his capacity as the Director of the Idaho Department of Water Resources. Respondents.	Case No. CV01-23-13173 **IGWA'S OBJECTION TO THE AGENCY RECORD AND TRANSCRIPT**
IN THE MATTER OF DISTRIBUTION OF WATER TO VARIOUS WATER RIGHTS HELD BY OR FOR THE BENEFIT OF A&B IRRIGATION DISTRICT, AMERICAN FALLS RESERVOIR DISTRICT #2, BURLEY IRRIGATION DISTRICT, MILNER IRRIGATION DISTRICT, MINIDOKA IRRIGATION DISTRICT, NORTH SIDE CANAL COMPANY, AND TWIN FALLS CANAL COMPANY	

Idaho Ground Water Appropriators, Inc. ("IGWA"), acting for and on behalf of North Snake Ground Water District, Magic Valley Ground Water District, Carey Valley Ground Water District, American Falls-Aberdeen Ground Water District, Jefferson-Clark Ground Water District, Madison Ground Water District, and Henry's Fork Ground Water District, through counsel, respectfully objects, pursuant to Rule 84(j) of the Idaho Rules of Civil Procedure and paragraph 7 of the Court's Procedural Order dated August 16, 2023, to the agency record and transcript filed by the Idaho Department of Water Resources ("Department") in this matter on August 30, 2023. There are two main reasons for this objection: (1) certain documents are missing from the record; and (2) certain pre-marked exhibits were duplicative and so the transcript should be clarified to reference the admitted exhibit.

INTRODUCTION

IGWA's Petition for Judicial Review challenges actions taken by the Idaho Department of Water Resources ("IDWR") in IDWR Docket No. CM-DC-2010-001, which is a contested case that began in 2005 and has been ongoing ever since. The contested case broadly involves the Surface Water Coalition (SWC) delivery call. This action involves one component of the contested case—the "Methodology Order" used to predict material injury and administer junior-priority groundwater rights under the SWC call.

The Methodology Order has undergone several amendments. IGWA's present petition for judicial review challenges the Fifth Methodology Order issued April 21, 2023, the April As-Applied Order issued the same day, and several orders issued in connection with an evidentiary hearing on the Fifth Methodology Order and the April As-Applied Order held in June of 2023.

Because this Fifth Methodology Order is the latest of a series of iterations of the Methodology Order, and because expert testimony at the hearing referenced prior versions of the Methodology Order, it is appropriate to include prior iterations of the Methodology Order in the agency record for judicial review. The Fourth Methodology Order was admitted at the hearing as Exhibit 306. Prior versions of the Methodology Orders were not admitted as evidence but were relied upon and referenced in IGWA's expert report (Exhibit 837A).

In addition, the agency record omits certain documents and a hearing transcript that were created in connection with IDWR Docket No. CM-DC-2010-001 and referenced in IGWA's Post-Hearing Brief filed June 16, 2023, in this matter.

DOCUMENTS MISSING FROM THE RECORD

The agency record filed by the Department did not include the following documents that IGWA seeks to have included because they are relevant to IGWA's petition for judicial review. Copies of these documents are attached hereto.

1. *Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover*, issued by the Department on April 7, 2010.

2. *Second Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover*, issued by the Department on June 23, 2010.

3. *Third Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover*, issued by the Department on April 16, 2015.

4. *Ground Water Districts' Brief in Support of Motion for Stay, Motion for Injunctive Relief, Motion to Compel, Motion for Expedited Decision, and Application to Show Cause*, filed May 19, 2023, in Ada County Case No. CV01-23-08187. This brief was incorporated by reference in section 4 of IGWA's Post-Hearing Brief.

5. *Declaration of Thomas J. Budge in Support of Ground Water Districts' Brief in Support of Motion for Stay, Motion for Injunctive Relief, Motion to Compel, Motion for Expedited Decision, and Application to Show Cause*, filed May 19, 2023, in Ada County Case No. CV01-23-08187. This declaration contains documents in the agency record that were cited and relied upon in IGWA's district court brief which, as explained above, is incorporated by reference in section 4 of IGWA's Post-Hearing Brief.

The documents cited in paragraphs number 4 and 5 pertain to IGWA's argument raised in prehearing filings, at the hearing, and in IGWA's post-hearing brief concerning the Department's non-compliance with the Idaho Administrative Procedure Act ("APA"), due process violations, and discovery violations. At the hearing, the Director shut down the presentation of evidence concerning these matters. First, at the onset of the hearing the Director reiterated his earlier limitation on materials and testimony made in the May 5, 2023 *Order Denying the Appointment of an Independent Hearing Officer and Motion for Continuance and Limiting Scope of Depositions* and *Notice of Materials Department Witnesses May Rely Upon At Hearing and Intent to Take Official Notice*, stating:

> [T]he testimony that I receive in this particular hearing will be limited to the factual components that were a part of the development and writing of the Fifth Methodology Order. . . . Now, there may be other areas that [sic] exploration that are outside of the methodology order, itself, and those areas if there is examination regarding those areas, I will allow objections. And will rule on those objections depending on the relevance to the Fifth Methodology Order.

Tr. Vol. I, 22:7-11; 19-24.

When Bingham Ground Water District attempted to make an offer of proof regarding the APA non-compliance and due process violations, to introduce two exhibits, Exhibits 340 and 354, the Director denied the offer in this exchange:

> Hearing Officer: Okay. Mr. Anderson, I'm not even accepting this. I will tell you that I am always meeting with staff trying to establish priorities as to what I need to work on and what I don't need to work on, and that's what I'm doing here.
>
> Mr. Anderson: Well, I'm not intending to try to make you a witness, Director. I just – this is information that was disclosed to us as a part of a request.
>
> Hearing Officer: That's fine. And we supplied this information in good faith, but I don't see anything in this that would either establish any nefarious intent or any reason to bring this document that was – I've never seen this document that I'm aware of. SWC discussion points, main discussion points, I've never seen any of this, and I think it's because it was part of settlement, and I was excluded from those discussions. So my string of emails here and what's included simply was an attempt on my part to say what do we need to prioritize and work on in the many responsibilities that the Department and the Director has, and that was the intent of these emails. And we disclosed them in good faith, and I guess, from my perspective, for you to even insinuate that there was something nefarious, I find to be offensive, and I won't let it in. Thank you.

Tr. Vol. IV, 1032:4-1033:5.

Notwithstanding, because IGWA not only raised these issues but also took a position on these issues, consistent with *County Highway District v. Brooke View, Inc*., 162 Idaho 138, 140-41 (2017), the issues are preserved for appeal. And the agency record should be augmented to include the documents referenced above so that IGWA can properly apprise the court of the issues on judicial review concerning compliance with the APA.

CORRECTION TO THE TRANSCRIPT

On May 30, 2023, a week before the start of the June 6th Department hearing, the parties submitted and exchanged witness lists and pre-marked exhibits. The pre-marked exhibits,

collectively, were numerous (approximately 250 documents identified). The parties attempted to identify and consolidate common exhibits, but time constraints hampered these efforts. As a result, Ms. Sukow was questioned and testified about Exhibit 197, however this exhibit was not admitted. Rather, Exhibit 829, which is substantially[1] the same as Exhibit 197, was admitted later. Ms. Sigsted also testified about Exhibit 829 but was also identified differently. To clarify the record, IGWA requests the following corrections be made to the transcript:

1. T. Vol. I, p. 76, L. 1-5:

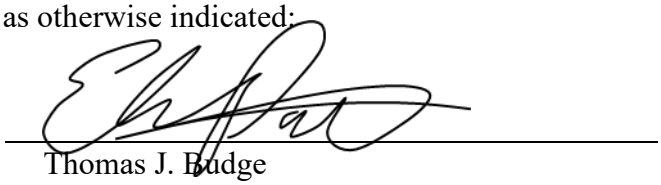
   (Exhibit ~~197~~ 829 marked.)

   Q. (BY MR. BUDGE) Let me have you turn to ~~Exhibit 197~~ Exhibit 829. Jennifer, do you recognize this document? It's labeled "~~Attachment 1,~~ Table 3-1. Results of Jaxon Higgs Analysis on IGWA's Proportionate Share ~~Modeling,~~ Related to Reach Gain Benefits and Acres Curtailed for the ~~May 2023 Curtailment~~ April 2023 As-Applied Order."?

2. T. Vol. III, p. 644, L. 16-18:

   Q: Thank you. Let's move next to Section 3.4.4, and if you can just explain this section and ~~the Table 3-1~~ Exhibit 829.

Respectfully submitted this 13th day of September, 2023.



RACINE OLSON, PLLP

IN THE MATTER OF THE DISTRIBUTION OF WATER TO VARIOUS WATER RIGHTS HELD BY AND FOR THE BENEFIT OF A&B IRRIGATION DISTRICT, AMERICAN FALLS RESERVOIR DISTRICT #2, BURLEY IRRIGATION DISTRICT, MILNER IRRIGATION DISTRICT, MINIDOKA IRRIGATION DISTRICT, NORTH SIDE CANAL COMPANY, AND TWIN FALLS CANAL COMPANY

TO: THE DISTRICT COURT AND THE PARTIES OF RECORD

On August 30, 2023, the Idaho Department of Water Resources ("Department") served its *Notice of Lodging the Agency Transcript and Record with the Agency* ("*Notice*") in this matter pursuant to I.R.C.P 84(j). The *Notice* gave the parties fourteen (14) days from the date of the *Notice* to file any objection to the agency transcript and record. On September 13, 2023, *IGWA's Objection to the Agency Record and Transcript* ("*IGWA's Objection*") was filed.

RESPONSE TO OBJECTION

A. Agency Record

IGWA's Objection requests that five documents be added to the record. These documents are:

1. *Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover*, issued by the Department on April 7, 2010.
2. *Second Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover*, issued by the Department on June 23, 2010.
3. *Third Amended Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover*, issued by the Department on April 16, 2015.
4. *Ground Water Districts' Brief in Support of Motion for Stay, Motion for Injunctive Relief, Motion to Compel, Motion for Expedited Decision, and Application to Show Cause*, filed May 19, 2023, in Ada County Case No. CV01-23-08187. This brief was incorporated by reference in section 4 of IGWA's Post-Hearing Brief.
5. *Declaration of Thomas J. Budge in Support of Ground Water Districts' Brief in Support of Motion for Stay, Motion for Injunctive Relief, Motion to Compel, Motion for Expedited Decision, and Application to Show Cause, filed May 19, 2023, in Ada County Case No. CV01-23-08187*.

IGWA states that the documents should be included in the record because "they are relevant to IGWA's petition for judicial review." *IGWA's Objection* at 3.

Idaho Rule of Civil Procedure 84(f)(1)(A) states "When statute provides what must be contained in the official record of the agency on judicial review, the agency must prepare the record as provided by statute."

Idaho Code § 67-5249(2) sets forth the scope of the agency record in this proceeding. It states:

> (2) The record shall include:
> (a) all notices of proceedings, pleadings, motions, briefs, petitions, and intermediate rulings;
> (b) evidence received or considered;
> (c) a statement of matters officially noticed;
> (d) offers of proof and objections and rulings thereon;
> (e) the record prepared by the presiding officer under the provisions of section 67-5242, Idaho Code, together with any transcript of all or part of that record;
> (f) staff memoranda or data submitted to the presiding officer or the agency head in connection with the consideration of the proceeding; and
> (g) any recommended order, preliminary order, final order, or order on reconsideration.

While subsection (2)(a) states the record shall include "briefs" and (2)(g) states the record shall include "any . . . final order," implicit in the statute is that the "briefs" and the "order" must have been submitted or issued as part of the administrative hearing. Otherwise, *all* briefs and *any* order from *any or all* legal matters must be included in the record. That interpretation of the statute is absurd.

After reviewing all five of IGWA's requested additions, the Director concludes that the documents identified by IGWA do not meet the criteria outlined in Idaho Code § 67-5249 because they were not briefs or final orders submitted as part of the administrative hearing. Accordingly, the Director finds the record should not include the documents.

B. Agency Transcript

IGWA's Objection seeks clarification of the record through "correction" of two portions of the agency transcript. *IGWA's Objection* at 5. *IGWA's Objection* does not contain any allegations that the agency transcript inaccurately reflects the testimony given during the administrative hearing. After reviewing IGWA's requested transcript

modifications, the Director concludes that the agency transcript accurately reflects the testimony given during the administrative hearing and finds that the agency transcript is accurate without modification. The concerns expressed by IGWA regarding exhibit numbers are best addressed in briefing, not by changing a transcript to something that does not accurately reflect the testimony.

ORDER

IT IS HEREBY ORDERED that the agency transcript and record are now deemed settled pursuant to I.R.C.P. 84(j).

IT IS FURTHER ORDERED that, pursuant to I.R.C.P. 84(j), *IGWA's Objection to the Agency Record and Transcript* and this order shall be included in the agency record on the petition for judicial review. The Department shall provide the parties with a copy of the settled agency transcript and record.

DATED this 27th day of September 2023.

NOTICE OF LODGING THE SETTLED AGENCY TRANSCRIPT AND RECORD WITH THE DISTRICT COURT

WENDELL, BONNEVILLE-JEFFERSON GROUND WATER DISTRICT, and BINGHAM GROUNDWATER DISTRICT, Intervenors.
IN THE MATTER OF THE DISTRIBUTION OF WATER TO VARIOUS WATER RIGHTS HELD BY AND FOR THE BENEFIT OF A&B IRRIGATION DISTRICT, AMERICAN FALLS RESERVOIR DISTRICT #2, BURLEY IRRIGATION DISTRICT, MILNER IRRIGATION DISTRICT, MINIDOKA IRRIGATION DISTRICT, NORTH SIDE CANAL COMPANY, AND TWIN FALLS CANAL COMPANY

TO: THE DISTRICT COURT AND THE PARTIES OF RECORD

On August 30, 2023, the Idaho Department of Water Resources ("Department") served its *Notice of Lodging the Agency Transcript and Record with the Agency* ("*Notice*") in this matter pursuant to I.R.C.P 84(j). The Notice gave the parties fourteen (14) days from the date of the *Notice* to file any objection to the agency transcript or record.

On September 13, 2023, *IGWA's Objection to the Agency Record and Transcript* was filed. IGWA requested certain additions to the agency record and corrections to the agency transcript. The Department's *Response to Objection; Order Settling the Agency Transcript and Record* is filed concurrently herewith, and the transcript and record are deemed settled pursuant to I.R.C.P. 84(j).

YOU ARE HEREBY NOTIFIED that the settled record is being filed with the District Court pursuant to I.R.C.P. 84(k), through iCourt e-filing and by providing one (1) DVD containing documents in OCR format, dated September 27, 2023. A copy of the agency transcript and record filed with the Department have been uploaded to the Department's website. The parties may visit https://idwr.idaho.gov/legal-actions/district-court-actions/igwa-v-idwr-

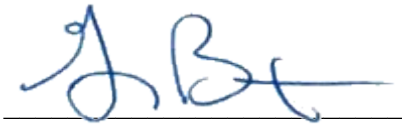
Attorneys for Respondent

IN THE DISTRICT COURT OF THE SEVENTH JUDICIAL DISTRICT OF THE STATE OF IDAHO, IN AND FOR THE COUNTY OF BINGHAM

JERRY D. BINGHAM and VALERIE H. BINGHAM, Petitioners, vs. IDAHO DEPARTMENT OF WATER RESOURCES, Respondent.	Case No. CV06-26-1801 **NOTICE OF LODGING THE AGENCY RECORD AND TRANSCRIPT WITH THE AGENCY**

TO: THE DISTRICT COURT AND THE PARTIES OF RECORD

In accordance with I.R.C.P. 84(j), YOU ARE HEREBY NOTIFIED that the agency record and transcript, having been prepared pursuant to Idaho Code § 67-5249 and I.R.C.P. 84(f)(1)(A), 84(g), and 84(i), are lodged with the Idaho Department of Water Resources for the purpose of settlement.



A copy of the agency record and transcript filed with the Department have been uploaded to the Department's website. The parties may visit https://idwr.idaho.gov/court-action/cv06-26-1801/ and follow their browser's document download procedure to obtain a copy of the agency

record and transcript after clicking on the PDFs titled "Agency Record on Appeal" and "Agency Transcript on Appeal," and the zipped data files titled "Agency Record Excel Files."

The parties have fourteen (14) days from the date of this notice to file any objections to the record or transcript. The agency's decision on any objection timely filed along with all evidence, exhibits, and written presentations on the objection shall be determined by the agency within fourteen (14) days and included in the record. If no objections are filed within that time, the record and transcript shall be deemed settled. Subsequently, the agency will lodge the settled record and transcript with the District Court pursuant to I.R.C.P. 84(k) and the Court's September 23, 2026 *Procedural Order*.

**Pro hac vice pending*

Attorneys for Petitioners

DISTRICT COURT OF THE STATE OF IDAHO

SEVENTH JUDICIAL DISTRICT

BINGHAM COUNTY

JERRY D. BINGHAM and VALERIE H. BINGHAM, Petitioners, vs. IDAHO DEPARTMENT OF WATER RESOURCES, Respondent, and IDAHO GROUND WATER APPROPRIATORS, INC., CITY OF	Case No. CV06-26-1801 **PETITIONERS' OBJECTIONS TO THE LODGED AGENCY RECORD**

POCATELLO, AMERICAN FALLS RESERVOIR DISTRICT #2, MINIDOKA IRRIGATION DISTRICT, A&B IRRIGATION DISTRICT, BURLEY IRRIGATION DISTRICT, MILNER IRRIGATION DISTRICT, NORTH SIDE CANAL COMPANY, TWIN FALLS CANAL COMPANY,

Intervenors.

Petitioners Jerry and Valerie Bingham, by and through their counsel of record, respectfully object, pursuant to Rule 84(j) of the Idaho Rules of Civil Procedure and paragraph 7 of the Court's Procedural Order, to the agency record lodged with Respondent Idaho Department of Water Resources ("Department") in this matter, as follows.

SPECIFIC GROUNDS FOR OBJECTION:
OMISSION OF REQUIRED EVIDENCE

Petitioners object to the omission from the lodged agency record in this case of the documents comprising the settled agency record for the Sixth Final Order Regarding Methodology, dated July 29, 2023—specifically, those documents listed at pages iv through xiii of the Settled Agency Record on Appeal, *Idaho Ground Water Appropriators, Inc. v. Idaho Dep't of Water Resources*, Case No. CV01-23-13173 (Fourth Judicial Dist. filed Sept. 27, 2023).[1] In the lodged record in this case, the Department included only the *Sixth Methodology Order* and the transcript of the associated administrative hearing, without including any of the record upon which the Department based the methodology order. The evidence considered and relied upon by the Department in reaching its findings of fact and conclusions of law in the *Sixth Methodology Order* is—as the Department itself has stated in its rejection of Petitioners' request for reconsideration, hearing, and stay—directly relevant to this Petition for Review. Under Idaho Code § 67-5249(3)(e), the agency record "shall include...[a]ll evidence received or considered" by the agency. As noted, the lodged record contains the *Sixth Methodology Order* itself and the related hearing transcript, but it omits the evidence the Department received or considered in issuing that order. This Court's review of the Department's *Sixth Methodology Order*, as it relates to Petitioners'

[1] The record is available at: https://idwr.idaho.gov/wp-content/uploads/sites/2/legal/CV01-23-13173/CV01-23-13173-20230927-Settled-Agency-Record-on-Appeal.pdf.

challenge to the Department's curtailment order, should include the record that the Department relied upon to formulate the methodology order. This record would materially assist the Court in determining whether the Department's methodology, and in turn the curtailment orders issued pursuant to the methodology, violate the Idaho law of prior appropriation. Accordingly, Petitioners request that the lodged record be augmented to include the documents comprising the settled agency record for the *Sixth Methodology Order*.

Petitioners also object to the omission of the Department's Staff Memorandum, dated December 30, 2025, filed with the Department's Notice of Compliance with Order to Provide Staff Memo in *In the Matter of Distribution of Water to Various Water Rights Held by or for the Benefit of A&B Irrigation District*, No. CM-DC-2010-001.[2] Idaho Code § 67-5249(3)(j) mandates that "[s]taff memoranda or data submitted to the presiding officer or the agency head in connection with the consideration of the proceeding" be included in the record. This Department staff memorandum outlines the calculation of curtailment priority dates relevant to the Department's curtailment orders issued pursuant to the delivery call of the Surface Water Coalition. The issues of how this calculation is determined, and the calculation's relationship to the law of prior appropriation, are central to Petitioners' challenge to the Department's curtailment order. Accordingly, Petitioners request that the lodged record be augmented to include the Department Staff Memorandum.

CONCLUSION

The lodged record is incomplete and insufficient under Idaho Code § 67-5249 without the evidence considered by the Department in adopting the governing *Sixth Methodology Order*, and the Departmental staff explanation as to which priority dates should be curtailed pursuant to the Surface Water Coalition's delivery call. Therefore, Petitioners respectfully object to the lodged record, and request that the Department include the foregoing documents in the settled agency record.

[2] The Department's Staff Memorandum is included within the appendix of documents filed in conjunction with Petitioners' motion to stay, *see* Decl. of Reed W. Larsen, Exh. C, and is available online at: https://idwr.idaho.gov/wp-content/uploads/sites/2/legal/CM-DC-2010-001/CM-DC-2010-001-20251230-Notice-of-Compliance-With-Order-to-Provide-Staff-Memo.pdf.

DATED: October 21, 2026.

Respectfully submitted,

Reed W. Larsen

Attorneys for Respondent

IN THE DISTRICT COURT OF THE SEVENTH JUDICIAL DISTRICT OF THE STATE OF IDAHO, IN AND FOR THE COUNTY OF BINGHAM

JERRY D. BINGHAM and VALERIE H. BINGHAM, Petitioners, vs. IDAHO DEPARTMENT OF WATER RESOURCES, Respondent, and IDAHO GROUND WATER APPROPRIATORS, INC., CITY OF POCATELLO, AMERICAN FALLS RESERVOIR DISTRICT #2, MINIDOKA IRRIGATION DISTRICT A&B IRRIGATION DISTRICT, BURLEY IRRIGATION DISTRICT, MILNER IRRIGATION DISTRICT, NORTH SIDE CANAL COMPANY, TWIN FALLS CANAL COMPANY, Intervenors.	Case No. CV06-26-1801 **AGENCY DECISION ON OBJECTION AND ORDER SETTLING THE AGENCY RECORD AND TRANSCRIPT**

On October 7, 2026, the Idaho Department of Water Resources ("Department") served its *Notice of Lodging the Agency Record and Transcript with the Agency* ("*Notice*") in this matter pursuant to I.R.C.P. 84(j)(1). The *Notice* gave the parties fourteen (14) days from the date of the

Notice to file any objection to the agency record or transcript. On October 21, 2026, Jerry and Valerie Bingham (the "Binghams") filed *Petitioners' Objections to the Lodged Agency Record* ("*Objection*"). No other objections were filed. In accordance with I.R.C.P. 84(j) and the Court's September 23, 2026 *Procedural Order*, the following constitutes the Department's decision on objections to the agency record and order settling the agency record and transcript.

In considering the *Objection*, the Department refers to Idaho Code § 67-5249(3), which governs the contents of an agency record on appeal; it states:

> The record shall include:
> (a) The recording of the hearing;
> (b) All notices of the hearing and other conferences conducted by the presiding officer;
> (c) All prehearing orders;
> (d) All motions, pleadings, briefs, petitions, requests, and intermediate rulings;
> (e) All evidence received or considered;
> (f) A statement of all matters officially noticed and any related notices;
> (g) All offers of proof and objections and rulings thereon;
> (h) All proposed findings and requested orders;
> (i) Any transcript of the hearing, if prepared;
> (j) Staff memoranda or data submitted to the presiding officer or the agency head in connection with the consideration of the proceeding;
> (k) Any recommended order, preliminary order, final order, or order on reconsideration; and
> (l) All matters placed on the record after an ex parte communication pursuant to section 67-5253, Idaho Code.

BACKGROUND

The agency record was prepared in connection with a request for judicial review of the Director's August 24, 2026 *Order Denying Jerry D. and Valerie H. Binghams' Petition for Reconsideration and Request for Hearing* and July 21, 2026 *Order Revising April 2026 Forecast Supply and Continuing May 14, 2026 Curtailment Order (Methodology Steps 5 & 6)*. *Pet. for Jud. Rev.* ¶ 3. Additionally, judicial review, "to the extent that such review is necessary and

collateral to review of the above-referenced orders," was also requested in connection with the following orders:

1. *Order Amending Curtailment List to Include Unmitigated Ground Water Rights*, issued June 17, 2026;
2. *Final Order Curtailing Ground Water Rights Junior to October 11, 1900*, issued May 14, 2026;
3. *Final Order Regarding April 2026 Forecast Supply (Methodology Steps 1–3)*, issued April 16, 2026;
4. *Final Order Curtailing Ground Water Rights Junior to August 15, 1952*, issued December 8, 2025;
5. *Final Order Establishing 2025 Reasonable Carryover (Methodology Step 9)*, issued November 21, 2025;
6. *Order Revising July 2025 Forecast Supply (Methodology Steps 7–8)*, issued September 11, 2025;
7. *Final Order Curtailing Ground Water Rights Junior to October 11, 1900*, issued July 25, 2025; and
8. *Sixth Final Order Regarding Methodology for Determining Material Injury to Reasonable In-Season Demand and Reasonable Carryover* ("*Sixth Methodology Order*"), issued July 19, 2023.

Id. ¶ 4.

ANALYSIS

The *Objection* is broken into two requests. First, the Binghams object to the omission of several hundred documents from the agency record related to the issuance of the *Sixth Methodology Order*. *Objection*, at 2. The Binghams specifically seek the inclusion of all documents listed on pages iv through xiii of the table of contents of the *Settled Agency Record on Appeal* filed in *Idaho Ground Water Appropriators, Inc. v. Idaho Department of Water Resources*, Ada County Case No. CV01-23-13173. *Id.* The Director finds that all independently listed documents on pages iv through xiii of the *Settled Agency Record on Appeal* relate to the issuance of the *Sixth Methodology Order*. In the interest of ensuring a complete record that

encompasses all evidence considered, this objection is sustained. These documents will be added to the record.

Second, the Binghams object to the omission of a December 30, 2025 Department staff memorandum from the agency record. *Objection*, at 3. The Binghams rely on Idaho Code § 67-5249(3)(j), which requires the agency record to include "[s]taff memoranda or data submitted to the presiding officer or the agency head in connection with the consideration of the proceeding." The Binghams' reliance on this provision is misplaced. The December 30, 2025 staff memorandum was requested by and submitted to Hearing Officer Gerald F. Schroeder, not to the Director. The Director issued all of the orders the Binghams seek to challenge in this judicial review proceeding, not Hearing Officer Schroeder. The memorandum was not submitted to or considered by the Director in connection with any of the orders the Binghams seek to challenge. Because the December 30, 2025 staff memorandum was submitted to Hearing Officer Schroeder and was not considered by the Director in issuing the orders challenged by the Binghams, it does not fall within the statutory requirement. Accordingly, the Binghams' objection to the omission of the December 30, 2025 Department staff memorandum is overruled and their request to augment the agency record with the memorandum is denied.

ORDER

IT IS HEREBY ORDERED that *Petitioners' Objections to the Lodged Agency Record* is sustained in part and overruled in part, consistent with the foregoing. The Department shall include in the agency record on appeal the documents for which the objection was sustained.

IT IS FURTHER ORDERED that pursuant to I.R.C.P. 84(j)(3), *Petitioners' Objections to the Lodged Agency Record* and this order shall be included in the agency record.

IT IS FURTHER ORDERED that with the additions to the record ordered above, the agency record and transcript are now deemed settled. In accordance with the Court's September 23, 2026 *Procedural Order*, the Department shall lodge the settled agency record and transcript on appeal with the Court no later than November 4, 2026.

DATED this 4th day of November 2026.

MATHEW WEAVER, Director
Idaho Department of Water Resources

Case No. CV06-26-1801 **NOTICE OF LODGING THE SETTLED AGENCY RECORD AND TRANSCRIPT WITH THE DISTRICT COURT**

On October 7, 2026, the Idaho Department of Water Resources ("Department") served its *Notice of Lodging the Agency Record and Transcript with the Agency* ("*Notice*") in this matter pursuant to I.R.C.P. 84(j)(1). The *Notice* gave the parties fourteen (14) days from the date of the *Notice* to file any objection to the agency record. On October 21, 2026, Jerry and Valerie

Bingham filed *Petitioners' Objections to the Lodged Agency Record*. No other objections were filed. On November 4, 2026, the Director issued his *Agency Decision on Objection and Order Settling the Agency Record and Transcript*. The agency record and transcript are now deemed settled.

YOU ARE HEREBY NOTIFIED that the settled agency record and transcript are being filed with the District Court pursuant to I.R.C.P. 84(k) and the Court's September 23, 2026 *Procedural Order*, through iCourt e-filing. However, pursuant to I.R.E.F.S. 5(o), the data files and officially noticed file folders included in the agency record have been placed on a USB flash drive and mailed to the Bingham County District Court for conventional filing.

A copy of the settled agency record and transcript filed with the Court, including the data files and officially noticed file folders, has been uploaded to the Department's website. The parties may visit https://idwr.idaho.gov/court-action/cv06-26-1801/ and follow their browser's document download procedure to obtain a copy of the settled agency record and transcript after clicking on the PDFs titled "Settled Agency Record on Appeal" and "Settled Agency Transcript on Appeal," and the zipped file titled "Settled Record Files."
